Can a computer be intelligent? What would it mean for a computer to be intelligent? John McCarthy, one of the founders of artificial intelligence research, once defined the field as “getting a computer to do things which, when done by people, are said to involve intelligence.” The point of the definition was that he felt perfectly comfortable about carrying on his research without first having to defend any particular philosophical view of what the word “intelligence” means.

There have always been two points of view among AI researchers about what their purpose is. One point of view is that AI programs contribute to our understanding of human psychology; when researchers take this view they try to make their programs reflect the actual mechanisms of intelligent human behavior. For example, Allen Newell and Herbert A. Simon begin their classic AI book Human Problem Solving with the sentence, “The aim of this book is to advance our understanding of how humans think.” In one of their research projects they studied cryptarithmetic problems, in which digits are replaced with letters in a multi-digit addition or multiplication. First they did a careful observation and analysis of how a human subject attacked such a problem, then they pointed out specific problem-solving techniques that the person used, and used those techniques as the basis for designing a computer simulation. The other point of view is that AI programs provide a more abstract model for intelligence in general; just as one can learn about the properties of computers by studying finite-state machines, even though no real computer operates precisely as a formal finite-state machine does, we can learn about the properties of any possible intelligent being by simulating intelligence in a computer program, whether or not the mechanisms of that program are similar to those used by people.

In the early days of AI research these two points of view were not sharply divided. Sometimes the same person would switch from one to the other, sometimes trying to model human thought processes and sometimes trying to solve a given problem by
whatever methods could be made to work. More recently, researchers who hold one or the other point of view consistently have begun to define two separate fields. One is *cognitive science*, in which computer scientists join with psychologists, linguists, biologists, and others to study human cognitive psychology, using computer programs as a concrete embodiment of theories about the human mind. The other is called *expert systems* or *knowledge engineering*, in which programming techniques developed by AI researchers are put to practical use in programs that solve real-world business problems such as the diagnosis and repair of malfunctioning equipment.

**Microworlds: Student**

In this chapter I’m going to concentrate on one particular area of AI research: teaching a computer to understand English. Besides its inherent interest, this area has the advantage that it doesn’t require special equipment, as do some other parts of AI such as machine vision and the control of robot manipulators.

In the 1950s many people were very optimistic about the use of computers to translate from one language to another. IBM undertook a government-sponsored project to translate scientific journals from Russian to English. At first they thought that this translation could be done very straightforwardly, with a Russian-English dictionary and a few little kludges to rearrange the order of words in a sentence to account for differences in the grammatical structure of the two languages. This simple approach was not successful. One problem is that the same word can have different meanings, and even different parts of speech, in different contexts. (According to one famous anecdote, the program translated the Russian equivalent of “The spirit is willing but the flesh is weak” into “The vodka is strong but the meat is rotten.”)

A decade later, several AI researchers had the idea that ambiguities in the meanings of words could be resolved by trying to understand English only in some limited context. If you know in advance that the sentence you’re trying to understand is about baseball statistics, or about relationships in a family tree, or about telling a robot arm to move blocks on a table (these are actual examples of work done in that period) then only certain narrowly defined types of sentences are meaningful at all. You needn’t think about metaphors or about the many assumptions about commonsense knowledge that people make in talking with one another. Such a limited context for a language understanding program is called a *microworld*.

This chapter includes a Logo version of Student, a program written by Daniel G. Bobrow for his 1964 Ph.D. thesis, *Natural Language Input for a Computer Problem Solving System*, at MIT. Student is a program that solves algebra word problems:
Microworlds: Student

? student [The price of a radio is $69.70. If this price is 15 percent less than the marked price, find the marked price.]

The marked price is 82 dollars

(In this illustration I’ve left out some of Student’s display of intermediate results.) The program has two parts: one that translates the word problem into the form of equations and another that solves the equations. The latter part is complex (about 40 Logo procedures) but straightforward; it doesn’t seem surprising to most people that a computer can manipulate mathematical equations. It is Student’s understanding of English sentences that furthered the cause of artificial intelligence.

The aim of the research reported here was to discover how one could build a computer program which could communicate with people in a natural language within some restricted problem domain. In the course of this investigation, I wrote a set of computer programs, the Student system, which accepts as input a comfortable but restricted subset of English which can be used to express a wide variety of algebra story problems...

In the following discussion, I shall use phrases such as “the computer understands English.” In all such cases, the “English” is just the restricted subset of English which is allowable as input for the computer program under discussion. In addition, for purposes of this report I have adopted the following operational definition of understanding. A computer understands a subset of English if it accepts input sentences which are members of this subset, and answers questions based on information contained in the input. The Student system understands English in this sense. [Bobrow, 1964.]

How does the algebra microworld simplify the understanding problem? For one thing, Student need not know anything about the meanings of noun phrases. In the sample problem above, the phrase The price of a radio is used as a variable name. The problem could just as well have been

The weight of a giant size detergent box is 69.70 ounces. If this weight is 15 percent less than the weight of an enormous size box, find the weight of an enormous size box.

For Student, either problem boils down to

\[ \text{variable1} = 69.70 \text{ units} \]

\[ \text{variable1} = 0.85 \times \text{variable2} \]

Find variable2.
How Student Translates English to Algebra

Student translates a word problem into equations in several steps. In the following paragraphs, I’ll mention in parentheses the names of the Logo procedures that carry out each step I describe, but don’t read the procedures yet. First read through the description of the process without worrying about the programming details of each step. Later you can reread this section while examining the complete listing at the end of the chapter.

In translating Student to Logo, I’ve tried not to change the capabilities of the program in any way. The overall structure of my version is similar to that of Bobrow’s original implementation, but I’ve changed some details. I’ve used iteration and mapping tools to make the program easier to read; I’ve changed some aspects of the fine structure of the program to fit more closely with the usual Logo programming style; in a few cases I’ve tried to make exceptionally slow parts of the program run faster by finding a more efficient algorithm to achieve the same goal.

The top-level procedure student takes one input, a list containing the word problem. (The disk file that accompanies this project includes several variables containing sample problems. For example,

? student :radio

will carry out the steps I’m about to describe.) Student begins by printing the original problem:

? student :radio

The problem to be solved is

The price of a radio is $69.70. If this price is 15 percent less than the marked price, find the marked price.

The first step is to separate punctuation characters from the attached words. For example, the word “price,” in the original problem becomes the two words “price ,” with the comma on its own. Then (student1) certain mandatory substitutions are applied (idioms). For example, the phrase percent less than is translated into the single word perless. The result is printed:

With mandatory substitutions the problem is
The price of a radio is 69.70 dollars. If this price is 15 percent less than the marked price, find the marked price.

(The word of in an algebra word problem can have two different meanings. Sometimes it means “times,” as in the phrase “one half of the population.” Other times, as in this problem, “of” is just part of a noun phrase like “the price of a radio.” The special word numof is a flag to a later part of the program and will then be further translated either into times or back into of. The original implementation of Student used, instead of a special word like numof, a “tagged” word represented as a list like [of / op]. Other examples of tagging are [Bill / person] and [has / verb].)

The next step is to separate the problem into simple sentences (bracket):

The simple sentences are

The price of a radio is 69.70 dollars.
This price is 15 percent less than the marked price.
Find the marked price.

Usually this transformation of the problem is straightforward, but the special case of “age problems” is recognized at this time, and special transformations are applied so that a sentence like

Mary is 24 years old.

is translated into

Mary's age is 24.

An age problem is one that contains any of the phrases as old as, age, or years old.

The next step is to translate each simple sentence into an equation or a variable whose value is desired as part of the solution (senform).

The equations to be solved are

Equal [price of radio] [product 69.7 [dollars]]
Equal [price of radio] [product 0.85 [marked price]]

The third simple sentence is translated, not into an equation, but into a request to solve these equations for the variable marked price.

The translation of simple sentences into equations is the most “intelligent” part of the program; that is, it’s where the program’s knowledge of English grammar and
vocabulary come into play and many special cases must be considered. In this example, the second simple sentence starts with the phrase this price. The program recognizes the word this (procedure nmtest) and replaces the entire phrase with the left hand side of the previous equation (procedure this).

**Pattern Matching**

Student analyzes a sentence by comparing it to several patterns (senform1). For example, one sentence form that Student understands is exemplified by these sentences:

Joe weighs 163 pounds.
The United States Army has 8742 officers.

The general pattern is

\[\text{something verb number unit}\].

Student treats such sentences as if they were rearranged to match

\[\text{The number of unit something verb is number} \].

and so it generates the equations

\[\text{Equal [number of pounds Joe weighs]} 163\]
\[\text{Equal [number of officers United States Army has]} 8742\]

The original version of Student was written in a pattern matching language called Meteor, which Bobrow wrote in Lisp. In Meteor, the instruction that handles this sentence type looks like this:

\[
(*\ (\ ($1 / \ verb)\ (\fn\ nmtest)\ $1\ (\$1 / \ dlm))\ 0
\ 
/\ (\ (*s\ shelf\ (*k\ equal\ (\fn\ opform\ (*k\ the\ number\ of\ 4\ 1\ 2))\n\ \ (\fn\ opform\ (*k\ 3\ 5\ 6))))\)\ return)
\]

The top line contains the pattern to be matched. In the pattern, a dollar sign represents zero or more words; the notation $1$ represents a single word. The zero at the end of the line means that the text that matches the pattern should be deleted and nothing should replace it. The rest of the instruction pushes a new equation onto a stack named shelf; that equation is formed out of the pieces of the matched pattern according to the numbers in the instruction. That is, the number 4 represents the fourth component of the pattern, which is $1$. 

Chapter 6 Artificial Intelligence
The pattern matcher I used for Student is the same as the one in Advanced Techniques, the second volume of this series.* Student often relies on the fact that Meteor’s pattern matcher finds the first substring of the text that matches the pattern, rather than requiring the entire text to match. Many patterns in the Logo version therefore take the form

```
[ "beg interesting part #end]
```

where the “interesting part” is all that appeared in the Meteor pattern.

Here is a very brief summary of the Logo pattern matcher included in this program. For a fuller description with examples, please refer to Volume 2. \texttt{Match} is a predicate with two inputs, both lists. The first input is the \texttt{pattern} and the second input is the \texttt{sentence}. \texttt{Match} outputs \texttt{true} if the sentence \texttt{matches} the pattern. A word in the pattern that does not begin with one of the special \texttt{quantiﬁer} characters listed below matches the identical word in the sentence. A word in the pattern that does begin with a quantiﬁer matches zero or more words in the sentence, as follows:

\begin{itemize}
\item \texttt{#} zero or more words
\item \texttt{&} one or more words
\item \texttt{?} zero or one word
\item \texttt{!} exactly one word
\item \texttt{@} zero or more words (test as group)
\item \texttt{^} zero or more words (as few as possible)
\end{itemize}

All quantifiers match as many consecutive words as possible while still allowing the remaining portion of the pattern to be matched, except for \texttt{^}. A quantifier may be used alone, or it can be followed by a variable name, a predicate name, or both:

\begin{itemize}
\item \texttt{#}
\item \texttt{#var}
\item \texttt{#:pred}
\item \texttt{#var:pred}
\end{itemize}

---

* The version in this project is modified slightly; the \texttt{match} procedure first does a fast test to try to reject an irrelevant pattern in \(O(n)\) time before calling the actual pattern matcher, which could take as much as \(O(2^n)\) time to reject a pattern, and which has been renamed \texttt{rmatch} (for “real match”) in this project.

---

\textit{Pattern Matching} 283
If a variable name is used, the word or words that match the quantifier will be stored in that variable if the match is successful. (The value of the variable if the match is not successful is not guaranteed.) If a predicate is used, it must take one word as input; in order for a word in the sentence to be accepted as (part of) a match for the quantifier, the predicate must output true when given that word as input. For example, the word

!factor: numberp

in the pattern above requires exactly one matching word in the sentence; that word must be a number, and it is remembered in the variable factor. If the quantifier is @ then the predicate must take a list as input, and it must output true for all the candidate matching words taken together as a list. For example, if you define a procedure

to threep :list
output equalp count :list 3
end

then the pattern word

@: threep

will match exactly three words in the sentence. (Student does not use this last feature of the pattern matcher. In fact, predicates are applied only to the single-word quantifiers ? and !.)

Pattern matching is also heavily used in converting words and phrases with mathematical meaning into the corresponding arithmetic operations (opform). An equation is a list of three members; the first member is the word equal and the other two are expressions formed by applying operations to variables and numbers. Each operation that is required is represented as a list whose first member is the name of the Logo procedure that carries out the operation and whose remaining members are expressions representing the operands. For example, the equation

\[ y = 3x^2 + 6x - 1 \]

would be represented by the list

[equal [y] [sum [product 3 [square [x]]] [product 6 [x]] [minus 1]]]

The variables are represented by lists like [x] rather than just the words because in Student a variable can be a multi-word phrase like price of radio. The difference between two expressions is represented by a sum of one expression and minus the other,
rather than as the difference of the expressions, because this representation turns out to make the process of simplifying and solving the equations easier.

In word problems, as in arithmetic expressions, there is a precedence of operations. Operations like squared apply to the variables right next to them; ones like times are intermediate, and ones like plus apply to the largest possible subexpressions. Student looks first for the lowest-priority ones like plus; if one is found, the entire rest of the clause before and after the operation word provide the operands. Those operands are recursively processed by opform; when all the low-priority operations have been found, the next level of priority will be found by matching the pattern

[^left !op:op1 #right]

---

**Solving the Equations**

Student uses the substitution technique to solve the equations. That is, one equation is rearranged so that the left hand side contains only a single variable and the right hand side does not contain that variable. Then, in some other equation, every instance of that variable is replaced by the right hand side of the first equation. The result is a new equation from which one variable has been eliminated. Repeating this process enough times should eventually yield an equation with only a single variable, which can be solved to find the value of that variable.

When a problem gives rise to several linear equations in several variables, the traditional technique for computer solution is to use matrix inversion; this technique is messy for human beings because there is a lot of arithmetic involved, but straightforward for computers because the algorithm can be specified in a simple way that doesn’t depend on the particular equations in each problem. Bobrow chose to use the substitution method because some problems give rise to equations that are linear in the variable for which a solution is desired but nonlinear in other variables. Consider this problem:

? student :tom

The problem to be solved is

If the number of customers Tom gets is twice the square of 20 per cent of the number of advertisements he runs, and the number of advertisements he runs is 45, what is the number of customers Tom gets?

With mandatory substitutions the problem is
If the number of customers Tom gets is 2 times the square 20 percent of the number of advertisements he runs, and the number of advertisements he runs is 45, what is the number of customers Tom gets?

The simple sentences are

The number of customers Tom gets is 2 times the square 20 percent of the number of advertisements he runs.
The number of advertisements he runs is 45.
What is the number of customers Tom gets?

The equations to be solved are

Equal [number of customers Tom gets]
  [product 2 [square [product 0.2 [number of advertisements he runs]]]]

Equal [number of advertisements he runs] 45

The number of customers Tom gets is 162

The problem is solved.

The first equation that Student generates for this problem is linear in the number of customers Tom gets, but nonlinear in the number of advertisements he runs. (That is, the equation refers to the square of the latter variable. An equation is linear in a given variable if that variable isn’t multiplied by anything other than a constant number.) Using the substitution method, Student can solve the problem by substituting the value 45, found in the second equation, for the number of advertisements variable in the first equation.

(Notice, in passing, that one of the special numof words in this problem was translated into a multiplication rather than back into the original word of.)

The actual sequence of steps required to solve a set of equations is quite intricate. I recommend taking that part of Student on faith the first time you read the program, concentrating instead on the pattern matching techniques used to translate the English sentences into equations. But here is a rough guide to the solution process. Both student1 and student2 call trysolve with four inputs: a list of the equations to solve, a list of the variables for which values are wanted, and two lists of units. A unit is a word or phrase like dollars or feet that may be part of a solution. Student treats units...
like variables while constructing the equations, so the combination of a number and a unit is represented as a product, like

[product 69.7 [dollars]]

for $69.70 in the first sample problem. While constructing the equations, Student generates two lists of units. The first, stored in the variable units, contains any word or phrase that appears along with a number in the problem statement, like the word feet in the phrase 3 feet (nmtest). The second, in the variable aunits, contains units mentioned explicitly in the find or how many sentences that tell Student what variables should be part of the solution (senform1). If the problem includes a sentence like

How many inches is a yard?

then the variable inches, and only that variable, is allowed to be part of the answer. If there are no aunits-type variables in the problem, then any of the units variables may appear in the solution (trysolve).

Trysolve first calls solve to solve the equations and then uses pranswers to print the results. Solve calls solver to do most of the work and then passes its output through solve.reduce for some final cleaning up. Solver works by picking one of the variables from the list :wanted and asking solvel to find a solution for that variable in terms of all the other variables—the other wanted variables as well as the units allowed in the ultimate answer. If solvel succeeds, then solver invokes itself, adding the newly-found expression for one variable to an association list (in the variable alis) so that, from then on, any occurrence of that variable will be replaced with the equivalent expression. In effect, the problem is simplified by eliminating one variable and eliminating one equation, the one that was solved to find the equivalent expression.

Solvel first looks for an equation containing the variable for which it is trying to find a solution. When it finds such an equation, the next task is to eliminate from that equation any variables that aren’t part of the wanted-plus-units list that solver gave solvel as an input. To eliminate these extra variables, solvel invokes solver with the extras as the list of wanted variables. This mutual recursion between solver and solvel makes the structure of the solution process difficult to follow. If solver manages to eliminate the extra variables by expressing them in terms of the originally wanted ones, then solvel can go on to substitute those expressions into its originally chosen equation and then use solveq to solve that one equation for the one selected variable in terms of all the other allowed variables. Solveq manipulates the equation more or less the way students in algebra classes do, adding the same term to both sides, multiplying both sides by the denominator of a polynomial fraction, and so on.
Here is how `solve` solves the radio problem. The equations, again, are

\[
\begin{align*}
\text{Equal [price of radio] [product 69.7 [dollars]]} \\
\text{Equal [price of radio] [product 0.85 [marked price]]}
\end{align*}
\]

`Trysolve` evaluates the expression

(1) `solve` [[marked price]]
    
    [[equal [price of radio] [product 69.7 [dollars]]]
     
     [[equal [price of radio] [product 0.85 [marked price]]] ]
     
     [[dollars]]

(I’m numbering these expressions so that I can refer to them later in the text.) The first input to `solve` is the list of variables wanted in the solution; in this case there is only one such variable. The second input is the list of two equations. The third is the list of unit variables that are allowed to appear in the solution; in this case only `[dollars]` is allowed. `Solver` evaluates

(2) `solver` [[marked price]] [[dollars]] [] []

(There is a fifth input, the word `insufficient`, but this is used only as an error flag if the problem can't be solved. To simplify this discussion I'm going to ignore that input for both `solver` and `solve1`.) `Solver` picks the first (in this case, the only) wanted variable as the major input to `solve1`:

(3) `solve1` [marked price]
    
    [[dollars]]
    
    []
    
    [[equal [price of radio] [product 69.7 [dollars]]]
     
     [[equal [price of radio] [product 0.85 [marked price]]] ]
     
     []

Notice that the first input to `solve1` is a single variable, not a list of variables. `Solve1` examines the first equation in the list of equations making up its fourth input. The desired variable does not appear in this equation, so `solve1` rejects that equation and invokes itself recursively:

(4) `solve1` [marked price]
    
    [[dollars]]
    
    []
    
    [[equal [price of radio] [product 0.85 [marked price]]]]
    
    [[equal [price of radio] [product 69.7 [dollars]]]]
This time, the first (and now only) equation on the list of candidates does contain the
desired variable. Solve1 removes that equation, not from its own list of equations
(:eqns), but from solve's overall list (:eqt). The equation, unfortunately, can’t be
solved directly to express [marked price] in terms of [dollars], because it contains
the extra, unwanted variable [price of radio]. We must eliminate this variable by
solving the remaining equations for it:

(5) solver [[price of radio]] [[marked price] [dollars]] [] []

As before, solver picks the first (again, in this case, the only) wanted variable and asks
solve1 to solve it:

(6) solve1 [price of radio]
    [[marked price] [dollars]]
    []
    [[equal [price of radio] [product 69.7 [dollars]]]]
    []

Solve1 does find the desired variable in the first (and only) equation, and this time
there are no extra variables. Solve1 can therefore ask solveq to solve the equation:

(7) solveq [price of radio]
    [equal [price of radio] [product 69.7 [dollars]]]

It isn’t part of solveq’s job to worry about which variables may or may not be part of the
solution; solve1 doesn’t call solveq until it’s satisfied that the equation is okay.

In this case, solveq has little work to do because the equation is already in the
desired form, with the chosen variable alone on the left side and an expression not
containing that variable on the right.

solveq (7) outputs [[price of radio] [product 69.7 [dollars]]
    to solve1 (6)

Solve1 appends this result to the previously empty association list.

solve1 (6) outputs [[[price of radio] [product 69.7 [dollars]]]
    to solver (5)

Solver only had one variable in its :wanted list, so its job is also finished.

solver (5) outputs [[[price of radio] [product 69.7 [dollars]]]
    to solve1 (4,3)
This outer invocation of solve1 was trying to solve for [marked price] an equation that also involved [price of radio]. It is now able to use the new association list to substitute for this unwanted variable an expression in terms of wanted variables only; this modified equation is then passed on to solveq:

(8) solveq [marked price]
    [equal [product 69.7 [dollars]] [product 0.85 [marked price]]]

This time solveq has to work a little harder, exchanging the two sides of the equation and dividing by 0.85.

solveq (8) outputs [[marked price] [product 82 [dollars]]]
    to solve1 (4,3)

Solve1 appends this result to the association list:

solve1 (4,3) outputs [[[price of radio] [product 69.7 [dollars]]]
    [[marked price] [product 82 [dollars]]]]
    to solver (2)

Since solver has no other wanted variables, it outputs the same list to solve, and solve outputs the same list to trysolve. (In this example, solve.reduce has no effect because all of the expressions in the association list are in terms of allowed units only. If the equations had been different, the expression for [price of radio] might have included [marked price] and then solve.reduce would have had to substitute and simplify (subord).)

It'll probably take tracing a few more examples and beating your head against the wall a bit before you really understand the structure of solve and its subprocedures. Again, don’t get distracted by this part of the program until you’ve come to understand the language processing part, which is our main interest in this chapter.

Age Problems

The main reason why Student treats age problems specially is that the English form of such problems is often expressed as if the variables were people, like “Bill,” whereas the real variable is “Bill’s age.” The pattern matching transformations look for proper names (personp) and insert the words s age after them (ageify). The first such age variable in the problem is remembered specially so that it can be substituted for pronouns (agepron). A special case is the phrase their ages, which is replaced (ageprob) with a list of all the age variables in the problem.
The problem to be solved is

Bill’s father’s uncle is twice as old as Bill’s father. 2 years from now Bill’s father will be 3 times as old as Bill. The sum of their ages is 92. Find Bill’s age.

With mandatory substitutions the problem is

Bill’s father’s uncle is 2 times as old as Bill’s father. 2 years from now Bill’s father will be 3 times as old as Bill. The sum of their ages is 92. Find Bill’s age.

The simple sentences are

Bill’s father’s uncle’s age is 2 times Bill’s father’s age.

Bill’s father’s age plus 2 is 3 times Bill’s age plus 2.

Sum Bill’s age and Bill’s father’s age and Bill’s father’s uncle’s age is 92.

Find Bill’s age.

The equations to be solved are

Equal [Bill’s father’s uncle’s age] [product 2 [Bill’s father’s age]]

Equal [sum [Bill’s father’s age] 2] [product 3 [sum [Bill’s age] 2]]

Equal [sum [Bill’s age] [sum [Bill’s father’s age] [Bill’s father’s uncle’s age]]] 92

Bill’s age is 8

The problem is solved.

(Note that in the original problem statement there is a space between the number 92 and the following period. I had to enter the problem in that form because of an inflexibility in Logo’s input parser, which assumes that a period right after a number is part of the number, so that “92.” is reformatted into 92 without the dot.)

Student represents the possessive word Bill’s as the two words Bill’s because this representation allows the pattern matcher to manipulate the possessive marker as a
The phrase 2 years from now in the original problem is first translated to in 2 years. This phrase is further processed according to where it appears in a sentence. When it is attached to a particular variable, in a phrase like Bill's age in 2 years, the entire phrase is translated into the arithmetic operation Bill's age plus 2 years (agewhen). (The special word plus is an addition operator, just like plus, except for its precedence; opform treats it as a tightly binding operation like squared instead of a loosely binding one like the ordinary plus.) When a phrase like in 2 years appears at the beginning of a sentence, it is remembered (agesen) as an implicit modifier for every age variable in that sentence that isn’t explicitly modified. In this example, in 2 years modifies both Bill's father's age and Bill's age. The special precedence of plus is needed in this example so that the equation will be based on the grouping

3 times [ Bill's age plus 2 ]

rather than

[ 3 times Bill's age ] plus 2

as it would be with the ordinary plus operator. You can also see how the substitution for their ages works in this example.

Here is a second sample age problem that illustrates a different kind of special handling:

? student :ann

The problem to be solved is

Mary is twice as old as Ann was when Mary was as old as Ann is now. If Mary is 24 years old, how old is Ann?

With mandatory substitutions the problem is

Mary is 2 times as old as Ann was when Mary was as old as Ann is now. If Mary is 24 years old, what is Ann?

The simple sentences are

Mary's age is 2 times Ann's age minus g1.

Mary's age minus g1 is Ann's age.
Mary’s age is 24.

What is Ann’s age?

The equations to be solved are

\[ \text{Equal} [\text{Mary’s age}] \cdot (\text{product} 2 \cdot (\text{sum} [\text{Ann’s age}] - \text{minus} [g1]))] \]

\[ \text{Equal} \cdot (\text{sum} [\text{Mary’s age}] - \text{minus} [g1]) \cdot \text{[Ann’s age]} \]

\[ \text{Equal} [\text{Mary’s age}] 24 \]

Ann’s age is 18.

The problem is solved.

What is new in this example is Student’s handling of the phrase was when in the sentence

Mary is 2 times as old as Ann was when Mary was as old as Ann is now.

Sentences like this one often cause trouble for human algebra students because they make implicit reference to a quantity that is not explicitly present as a variable. The sentence says that Mary’s age now is twice Ann’s age some number of years ago, but that number is not explicit in the problem. Student makes this variable explicit by using a generated symbol like the word \text{g1} in this illustration. Student replaces the phrase was when with the words

was \text{g1} years ago. \text{g1} years ago

This substitution (in \text{ageprob}) happens before the division of the problem statement into simple sentences (\text{bracket}). As a result, this one sentence in the original problem becomes the two sentences

Mary’s age is 2 times Ann’s age \text{g1} years ago.

\text{g1} years ago Mary’s age was Ann’s age now.

The phrase \text{g1 years ago} in each of these sentences is further processed by \text{agesen} and \text{agewhen} as discussed earlier; the final result is

Mary’s age is 2 times Ann’s age minus \text{g1}.

Mary’s age minus \text{g1} is Ann’s age.

Age Problems
A new generated symbol is created each time this situation arises, so there is no conflict from trying to use the same variable name for two different purposes. The phrase will be when is handled similarly, except that the translated version is

\[
\text{in } g2 \text{ years} . \text{ in } g2 \text{ years}
\]

**AI and Education**

These decoupling heuristics are useful not only for the Student program but for people trying to solve age problems. The classic age problem about Mary and Ann, given above, took an MIT graduate student over 5 minutes to solve because he did not know this heuristic. With the heuristic he was able to set up the appropriate equations much more rapidly. As a crude measure of Student’s relative speed, note that Student took less than one minute to solve this problem.

This excerpt from Bobrow’s thesis illustrates the idea that insights from artificial intelligence research can make a valuable contribution to the education of human beings. An intellectual problem is solved, at least in many cases, by dividing it into pieces and developing a technique for each subproblem. The subproblems are the same whether it is a computer or a person trying to solve the problem. If a certain technique proves valuable for the computer, it may be helpful for a human problem solver to be aware of the computer’s methods. Bobrow’s suggestion to teach people one specific heuristic for algebra word problems is a relatively modest example of this general theme. (A heuristic is a rule that gives the right answer most of the time, as opposed to an algorithm, a rule that always works.) Some researchers in cognitive science and education have proposed the idea of *intelligent CAI* (computer assisted instruction), in which a computer would be programmed as a “tutor” that would observe the efforts of a student in solving a problem. The tutor would know about some of the mistaken ideas people can have about a particular class of problem and would notice a student falling into one of those traps. It could then offer advice tailored to the needs of that individual student.

The development of the Logo programming language (and so also, indirectly, this series of books) is another example of the relationship between AI and education. Part of the idea behind Logo is that the process of programming a computer resembles, in some ways, the process of teaching a person to do something. (This can include teaching oneself.) For example, when a computer program doesn’t work, the experienced programmer doesn’t give up in despair, but instead * debugs* the program. Yet many students are willing to give up and say “I just don’t get it” if their understanding of some problem isn’t perfect on the first try.
The critic is afraid that children will adopt the computer as model and eventually come to “think mechanically” themselves. Following the opposite tack, I have invented ways to take educational advantage of the opportunities to master the art of *deliberately* thinking like a computer; according, for example, to the stereotype of a computer program that proceeds in a step-by-step, literal, mechanical fashion. There are situations where this style of thinking is appropriate and useful. Some children’s difficulties in learning formal subjects such as grammar or mathematics derive from their inability to see the point of such a style.

A second educational advantage is indirect but ultimately more important. By deliberately learning to imitate mechanical thinking, the learner becomes able to articulate what mechanical thinking is and what it is not. The exercise can lead to greater confidence about the ability to choose a cognitive style that suits the problem. Analysis of “mechanical thinking” and how it is different from other kinds and practice with problem analysis can result in a new degree of intellectual sophistication. By providing a very concrete, down-to-earth model of a particular style of thinking, work with the computer can make it easier to understand that there is such a thing as a “style of thinking.” And giving children the opportunity to choose one style or another provides an opportunity to develop the skill necessary to choose between styles. Thus instead of inducing mechanical thinking, contact with computers could turn out to be the best conceivable antidote to it. And for me what is most important in this is that through these experiences these children would be serving their apprenticeships as epistemologists, that is to say learning to think articulately about thinking. [Seymour Papert, *Mindstorms*, Basic Books, 1980, p. 27.]

### Combining Sentences Into One Equation

In age problems, as we’ve just seen, a single sentence may give rise to two equations. Here is an example of the opposite, several sentences that together contribute a single equation.

```imperative
? student :nums

The problem to be solved is

A number is multiplied by 6. This product is increased by 44. This result is 68. Find the number.
```
With mandatory substitutions the problem is

A number ismulby 6 . This product is increased by 44 . This result is 68 . Find the number .

The simple sentences are

A number ismulby 6 .

This product is increased by 44 .

This result is 68 .

Find the number .

The equations to be solved are

The number is 4

The problem is solved.

Student recognizes problems like this by recognizing the phrases “is multiplied by,” “is divided by,” and “is increased by” (senform1). A sentence containing one of these phrases is not translated into an equation; instead, a partial equation is saved until the next sentence is read. That next sentence is expected to start with a phrase like “this result” or “this product.” The same procedure (this) that in other situations uses the left hand side of the last equation as the expression for the this-phrase notices that there is a remembered partial equation and uses that instead. In this example, the sentence

A number ismulby 6 .

remembers the algebraic expression

[product [number] 6]

The second sentence uses that remembered expression as part of a new, larger expression to be remembered:

[sum [product [number] 6] 44]

The third sentence does not contain one of the special “is increased by” phrases, but is instead a standard “A is B” sentence. That sentence, therefore, does give rise to an equation, as shown above.
Perhaps the most interesting thing to notice about this category of word problem is how narrowly defined Student’s criterion for recognizing the category is. Student gets away with it because algebra word problems are highly stereotyped; there are just a few categories, with traditional, standard wordings. In principle there could be a word problem starting

Robert has a certain number of jelly beans. This number is twice the number of jelly beans Linda has.

These two sentences are together equivalent to

The number of jelly beans Robert has is twice the number of jelly beans Linda has.

But Student would not recognize the situation because the first sentence doesn’t talk about “is increased by.” We could teach Student to understand a word problem in this form by adding the instruction

if match ["one !verb1:verb a certain number of #stuff1 !:dlm] :sent
    [push "ref opform (se [the number of] :stuff1 :one :verb1)"
        op [[]]
along with the other known sentence forms in senform1. (Compare this to the pattern matching instruction shown earlier for a similar sentence but with an explicitly specified number.)

Taking advantage of the stereotyped nature of word problems is an example of how the microworld strategy helped make the early AI programs possible. If word problems were expressed with all the flexibility of language in general, Student would need many more sentence patterns than it actually has. (How many different ways can you think of to express the same idea about Robert and Linda? How many of those ways can Student handle?)

Allowing Flexible Phrasing

In the examples we’ve seen so far, Student has relied on the repetition of identical or near-identical phrases such as “the marked price” or “the number of advertisements he runs.” (The requirement is not quite strictly identical phrases because articles are removed from the noun phrases to make variable names.) In real writing, though, such phrases are often abbreviated when they appear for a second time. Student will translate such a problem into a system of equations that can’t be solved, because what should be one variable is instead a different variable in each equation. But Student can recognize
this situation and apply heuristic rules to guess that two similar variable names are meant, in fact, to represent the same variable. (Some early writers on AI considered the use of heuristic methods one of the defining characteristics of the field. Computer scientists outside of AI were more likely to insist on fully reliable algorithms. This distinction still has some truth to it, but it isn’t emphasized so much as a critical issue these days.) Student doesn’t try to equate different variables until it has first tried to solve the equations as they are originally generated. If the first attempt at solution fails, Student has recourse to less certain techniques (student2 calls vartest).

? student :sally

The problem to be solved is

The sum of Sally’s share of some money and Frank’s share is $4.50. Sally’s share is twice Frank’s. Find Frank’s and Sally’s share.

With mandatory substitutions the problem is

sum Sally s share numof some money and Frank s share is 4.50 dollars . Sally s share is 2 times Frank s . Find Frank s and Sally s share .

The simple sentences are

Sum Sally s share numof some money and Frank s share is 4.50 dollars . Sally s share is 2 times Frank s . Find Frank s and Sally s share .

The equations to be solved are

Equal [sum [Sally s share of some money] [Frank s share]] [product 4.50 [dollars]]

Equal [Sally s share] [product 2 [Frank s]]

The equations were insufficient to find a solution.

Assuming that
Frank s is equal to [Frank s share]

Assuming that
[Sally s share] is equal to [Sally s share of some money]

Frank s is 1.5 dollars
Sally’s share is 3 dollars

The problem is solved.

In this problem Student has found two pairs of similar variable names. When it finds such a pair, Student adds an equation of the form

\[ \text{equal} \ variable_1 \ variable_2 \]

to the previous set of equations. In both of the pairs in this example, the variable that appears later in the problem statement is entirely contained within the one that appears earlier.

Another point of interest in this example is that the variable \texttt{dollars} is included in the list of units that may be part of the answer. The word problem does not explicitly ask “How many dollars is Sally’s share,” but because one of the sentences sets an expression equal to “4.50 dollars” Student takes that as implicit permission to express the answer in dollars.

The only other condition under which Student will consider two variables equal is if their names are identical except that some phrase in the one that appears earlier is replaced with a pronoun in the one that appears later. That is, a variable like \texttt{the number of ice cream cones the children eat} will be considered equal to a later variable \texttt{the number of ice cream cones they eat}. Here is a problem in which this rule is applied:

? student :guns

The problem to be solved is

The number of soldiers the Russians have is one half of the number of guns they have. They have 7000 guns. How many soldiers do they have?

With mandatory substitutions the problem is

The number numof soldiers the Russians have is 0.5 numof the number numof guns they have. They have 7000 guns. Howm soldiers do they have?

The simple sentences are

The number numof soldiers the Russians have is 0.5 numof the number numof guns they have.

They have 7000 guns.
Howm soldiers do they have?

The equations to be solved are

Equal [number of soldiers Russians have]
   [product 0.5 [number of guns they have]]

Equal [number of guns they have] 7000

The equations were insufficient to find a solution.

Assuming that
   [number of soldiers they have] is equal to
       [number of soldiers Russians have]

The number of soldiers they have is 3500
The problem is solved.

Using Background Knowledge

In some word problems, not all of the necessary information is contained within the problem statement itself. The problem requires the student to supply some piece of general knowledge about the world in order to determine the appropriate equations. This knowledge may be about unit conversions (one foot is 12 inches) or about relationships among physical quantities (distance equals speed times time). Student “knows” some of this background information and can apply it (geteqns) if the equations determined by the problem statement are insufficient.

? student :jet

The problem to be solved is

The distance from New York to Los Angeles is 3000 miles. If the average speed of a jet plane is 600 miles per hour, find the time it takes to travel from New York to Los Angeles by jet.

With mandatory substitutions the problem is

The distance from New York to Los Angeles is 3000 miles. If the average speed of a jet plane is 600 miles per hour, find the time it takes to travel from New York to Los Angeles by jet.

The simple sentences are
The distance from New York to Los Angeles is 3000 miles.
The average speed of a jet plane is 600 miles per hour.

Find the time it takes to travel from New York to Los Angeles by jet.

The equations to be solved are

Equal [distance from New York to Los Angeles] [product 3000 [miles]]

Equal [average speed of jet plane] [quotient [product 600 [miles]] [product 1 [hours]]]

The equations were insufficient to find a solution.

Using the following known relationships

Equal [distance] [product [speed] [time]]

Equal [distance] [product [gas consumption] [number of gallons of gas used]]

Assuming that [speed] is equal to [average speed of jet plane]

Assuming that [time] is equal to [time it takes to travel from New York to Los Angeles by jet]

Assuming that [distance] is equal to [distance from New York to Los Angeles]

The time it takes to travel from New York to Los Angeles by jet is 5 hours.

The problem is solved.

Student’s library of known relationships is indexed according to the first word of the name of each variable involved in the relationship. (If a variable starts with the words number of it is indexed under the following word.) The relationships, in the form of equations, are stored in the property lists of these index words.

Property lists are also used to keep track of irregular plurals and the corresponding singulars. Student tries to keep all units in plural form internally, so that if a problem refers to both 1 foot and 2 feet the same variable name will be used for both. (That is, the first of these will be translated into

*Using Background Knowledge*
in Student’s internal representation. Then the opposite translation is needed if the product of 1 and some unit appears in an answer to be printed.

The original Student also used property lists to remember the parts of speech of words and the precedence of operators, but because of differences in the syntax of the Meteor pattern matcher and my Logo pattern matcher I’ve found it easier to use predicate operations for that purpose.

The original Student system included a separately invoked remember procedure that allowed all these kinds of global information to be entered in the form of English sentences. You’d say

Feet is the plural of foot

or

Distance equals speed times time

and remember would use patterns much like those used in understanding word problems to translate these sentences into pprop instructions. Since Lisp programs, like Logo programs, can themselves be manipulated as lists, remember could even accept information of a kind that’s stored in the Student program itself, such as the wording transformations in idioms, and modify the program to reflect this information. I haven’t bothered to implement that part of the Student system because it takes up extra memory and doesn’t exhibit any new techniques.

As the above example shows, it’s important that Student’s search for relevant known relationships comes before the attempt to equate variables with similar names. The general relationship that uses a variable named simply [distance] doesn’t help unless Student can identify it as relevant to the variable named [distance from New York to Los Angeles] in the specific problem under consideration.

Here is another example in which known relationships are used:

? student :span

The problem to be solved is

If 1 span is 9 inches, and 1 fathom is 6 feet, how many spans is 1 fathom?

With mandatory substitutions the problem is
If 1 span is 9 inches, and 1 fathom is 6 feet, how many spans is 1 fathom?

The simple sentences are
1 span is 9 inches.
1 fathom is 6 feet.
How many spans is 1 fathom?

The equations to be solved are
Equal [product 1 [spans]] [product 9 [inches]]
Equal [product 1 [fathoms]] [product 6 [feet]]
Equal g2 [product 1 [fathoms]]

The equations were insufficient to find a solution.

Using the following known relationships
Equal [product 1 [yards]] [product 3 [feet]]
Equal [product 1 [feet]] [product 12 [inches]]

1 fathom is 8 spans
The problem is solved.

Besides the use of known relationships, this example illustrates two other features of Student. One is the use of an explicitly requested unit in the answer. Since the problem asks
How many spans is 1 fathom?

Student knows that the answer must be expressed in spans. Had there been no explicit request for a particular unit, all the units that appear in phrases along with a number would be eligible to appear in the answer: inches, feet, and fathoms. Student might then blithely inform us that
1 fathom is 1 fathom
The problem is solved.
The other new feature demonstrated by this example is the use of a generated symbol to represent the desired answer. In the statement of this problem, there is no explicit variable representing the unknown. [Fathoms] is a unit, not a variable for which a value could be found. The problem asks for the value of the expression

\[ \text{[product 1 [fathoms]]} \]

in terms of spans. Student generates a variable name (\( g_2 \)) to represent the unknown and produces an equation

\[ \text{[equal } g_2 \text{ [product 1 [fathoms]]} \]

to add to the list of equations. A generated symbol will be needed whenever the “Find” or “What is” sentence asks for an expression rather than a simple variable name. For example, an age problem that asks “What is the sum of their ages” would require the use of a generated symbol. (The original Student always used a generated symbol for the unknowns, even if there was already a single variable in the problem representing an unknown. It therefore had equations like

\[ \text{[equal } g_3 \text{ [marked price]} \]

in its list, declaring one variable equal to another. I chose to check for this case and avoid the use of a generated symbol because the time spent in the actual solution of the equations increases quadratically with the number of equations.)

---

**Optional Substitutions**

We have seen many cases in which Student replaces a phrase in the statement of a problem with a different word or phrase that fits better with the later stages of processing, like the substitution of 2 times for twice or a special keyword like perless for percent less than. Student also has a few cases of optional substitutions that may or may not be made (tryidiom).

There are two ways in which optional substitutions can happen. One is exemplified by the phrase the perimeter of the rectangle. Student first attempts the problem without any special processing of this phrase. If a solution is not found, Student then replaces the phrase with twice the sum of the length and width of the rectangle and processes the resulting new problem from the beginning. Unlike the use of known relationships or similarity of variable names, which Student handles by adding to the already-determined equations, this optional substitution requires the
entire translation process to begin again. For example, the word *twice* that begins the replacement phrase will be further translated to *2 times*.

The second category of optional substitution is triggered by the phrase *two numbers*. This phrase must always be translated to something, because it indicates that two different variables are needed. But the precise translation depends on the wording of the rest of the problem. Student tries two alternative translations: *one of the numbers* and the *other number* and one *number* and the *other number*. Here is an example in which the necessary translation is the one Student tries second:

? **student :sumtwo**

The problem to be solved is

The sum of two numbers is 96, and one number is 16 larger than the other number. Find the two numbers.

The problem with an idiomatic substitution is

The sum of one of the numbers and the other number is 96, and one number is 16 larger than the other number. Find the one of the numbers and the other number.

With mandatory substitutions the problem is

sum one num of the numbers and the other number is 96, and one number is 16 plus the other number. Find the one num of the numbers and the other number.

The simple sentences are

Sum one num of the numbers and the other number is 96.
One number is 16 plus the other number.
Find the one num of the numbers and the other number.

The equations to be solved are

Equal [sum [one of numbers] [other number]] 96
Equal [one number] [sum 16 [other number]]

The equations were insufficient to find a solution.
The problem with an idiomatic substitution is

The sum of one number and the other number is 96, and one number is 16 larger than the other number. Find the one number and the other number.

With mandatory substitutions the problem is

sum one number and the other number is 96, and one number is 16 plus the other number. Find the one number and the other number.

The simple sentences are

sum one number and the other number is 96.

One number is 16 plus the other number.

Find the one number and the other number.

The equations to be solved are

Equal [sum [one number] [other number]] 96
Equal [one number] [sum 16 [other number]]

The one number is 56
The other number is 40
The problem is solved.

There is no essential reason why Student uses one mechanism rather than another to deal with a particular problematic situation. The difficulties about perimeters and about the phrase “two numbers” might have been solved using mechanisms other than this optional substitution one. For example, the equation

[equal [perimeter] [product 2 [sum [length] [width]]]]

might have been added to the library of known relationships. The difficulty about alternate phrasings for “two numbers” could be solved by adding

[[one of the :word:pluralp] ["one singular :word"]]

to the list of idiomatic substitutions in idiom.

Not all the mechanisms are equivalent, however. The “two numbers” problem couldn’t be solved by adding equations to the library of known relationships, because...
If All Else Fails

Sometimes Student fails to solve a problem because the problem is beyond either its linguistic capability or its algebraic capability. For example, Student doesn’t know how to solve quadratic equations. But sometimes a problem that Student could solve in principle stumps it because it happens to lack a particular piece of common knowledge. When a situation like that arises, Student is capable of asking the user for help (student2).

? student :ship

The problem to be solved is

The gross weight of a ship is 20000 tons. If its net weight is 15000 tons, what is the weight of the ships cargo?

With mandatory substitutions the problem is

The gross weight numof a ship is 20000 tons . If its net weight is 15000 tons , what is the weight numof the ships cargo ?

The simple sentences are

The gross weight numof a ship is 20000 tons .

Its net weight is 15000 tons .

What is the weight numof the ships cargo ?

The equations to be solved are

Equal [gross weight of ship] [product 20000 [tons]]

Equal [its net weight] [product 15000 [tons]]

The equations were insufficient to find a solution.

Do you know any more relationships among these variables?

Weight of ships cargo

If All Else Fails 307
The weight of a ship's cargo is the gross weight minus the net weight.

Assuming that net weight is equal to its net weight.
Assuming that gross weight is equal to gross weight of ship.
The weight of the ship's cargo is 5000 tons.
The problem is solved.

Limitations of Pattern Matching

Student relies on certain stereotyped forms of sentences in the problems it solves. It's easy to make up problems that will completely bewilder it:

Suppose you have 14 jelly beans. You give 2 each to Tom, Dick, and Harry. How many do you have left?

The first mistake Student makes is that it thinks the word and following a comma separates two clauses; it generates simple sentences.
You give 2 each to Tom, Dick, Harry.

This is quite a fundamental problem; Student's understanding of the difference between a phrase and a clause is extremely primitive and prone to error. Adding another pattern won't solve this one; the trouble is that Student pays no attention to the words in between the key words like and.

There are several other difficulties with this problem, some worse than others. Student doesn't recognize the word suppose as having a special function in the sentence, so it makes up a noun phrase suppose you just like the russians. This could be fixed with an idiomatic substitution that just ignored suppose. Another relatively small problem is that the sentence starting how many doesn't say how many of what; Student needs a way to understand that the relevant noun phrase is jelly beans and not, for example, Tom. The words give (representing subtraction) and each (representing...
Limitations of Pattern Matching

The pattern matcher used in Student is equivalent to a finite-state machine. The important thing to note about the patterns used in Student is that they only apply predicates to one word at a time, not to groups of words. In other words, they don’t use the *quantifier. Here is a typical student pattern:

```
[^ what !:in [is are] #one !:dlm]
```

For the purposes of this discussion, you can ignore the fact that the pattern matcher can set variables to remember which words matched each part of the pattern. In comparing a pattern matcher to a finite-state machine, the question we’re asking is what categories of strings can the pattern matcher accept. This particular pattern is equivalent to the following machine:

The arrow that I’ve labeled *dlm* is actually several arrows connecting the same states, one for each symbol that the predicate *dlm* accepts, i.e., period, question mark, and semicolon. Similarly, the arrows labeled *any* are followed for any symbol at all. This machine is nondeterministic, but you’ll recall that that doesn’t matter; we can turn it into a deterministic one if necessary.
To be sure you understand the equivalence of patterns and finite-state machines, see if you can draw a machine equivalent to this pattern:

\[ I \text{ see } !:i \text{ in } \{ \text{the a an}\} \ ?:\text{numberp} \ &:\text{adjective} \ !:\text{noun} \ #:\text{adverb} \]

This pattern uses all the quantifiers that test words one at a time.

If these patterns are equivalent to finite-state machines, you’d expect them to have trouble recognizing sentences that involve embedding of clauses within clauses, since these pose the same problem as keeping track of balancing of parentheses. For example, a sentence like “The book that the boy whom I saw yesterday was reading is interesting” would strain the capabilities of a finite-state machine. (As in the case of parentheses, we could design a FSM that could handle such sentences up to some fixed depth of embedding, but not one that could handle arbitrarily deep embedding.)

**Context-Free Languages**

If we allow the use of the \$ quantifier in patterns, and if the predicates used to test substrings of the sentences are true functions without side effects, then the pattern matcher is equivalent to an RTN or a production rule grammar. What makes an RTN different from a finite-state machine is that the former can include arrows that match several symbols against another (or the same) RTN. Equivalently, the \$ quantifier matches several symbols against another (or the same) pattern.

A language that can be represented by an RTN is called a context-free language. The reason for the name is that in such a language a given string consistently matches or doesn’t match a given predicate regardless of the rest of the sentence. That’s the point of what I said just above about side effects; the output from a test predicate can’t depend on anything other than its input. Pascal is a context-free language because

\[ \text{this} := \text{that} \]

is always an assignment statement regardless of what other statements might be in the program with it.

What isn’t a context-free language? The classic example in automata theory is the language consisting of the strings

abc
aabbcc
aaabbbcccc
aaaabbbcccc
and so on, with the requirement that the number of as be equal to the number of bs and also equal to the number of cs. That language can’t be represented as RTNs or production rules. (Try it. Don’t confuse it with the language that accepts any number of as followed by any number of bs and so on; even a finite-state machine can represent that one. The equal number requirement is important.)

The classic formal system that can represent any language for which there are precise rules is the Turing machine. Its advantage over the RTN is precisely that it can “jump around” in its memory, looking at one part while making decisions about another part.

There is a sharp theoretical boundary between context-free and context-sensitive languages, but in practice the boundary is sometimes fuzzy. Consider again the case of Pascal and that assignment statement. I said that it’s recognizably an assignment statement because it matches a production rule like

```
assignment  :  identifier := expression
```

(along with a bunch of other rules that determine what qualifies as an expression). But that production rule doesn’t really express all the requirements for a legal Pascal assignment statement. For example, the identifier and the expression must be of the same type. The actual Pascal compiler (any Pascal compiler, not just mine) includes instructions that represent the formal grammar plus extra instructions that represent the additional requirements.

The type agreement rule is an example of context sensitivity. The types of the relevant identifiers were determined in var declarations earlier in the program; those declarations are part of what determines whether the given string of symbols is a legal assignment.

**Augmented Transition Networks**

One could create a clean formal description of Pascal, type agreement rules and all, by designing a Turing machine to accept Pascal programs. However, Turing machines aren’t easy to work with for any practical problem. It’s much easier to set up a context-free grammar for Pascal and then throw in a few side effects to handle the context-sensitive aspects of the language.

Much the same is true of English. It’s possible to set up an RTN (or a production rule grammar) for noun phrases, for example, and another one for verb phrases. It’s tempting then to set up an RTN for a sentence like this:
This machine captures some, but not all, of the rules of English. It’s true that a sentence requires a noun phrase (the subject) and a verb phrase (the predicate). But there are agreement rules for person and number (I run but he runs) analogous to the type agreement rules of Pascal.

Some artificial intelligence researchers, understanding all this, parse English sentences using a formal description called an augmented transition network (ATN). An ATN is just like an RTN except that each transition arrow can have associated with it not only the name of a symbol or another RTN but also some conditions that must be met in order to follow the arrow and some actions that the program should take if the arrow is followed. For example, we could turn the RTN just above into an ATN by adding an action to the first arrow saying “store the number (singular or plural) of the noun phrase in the variable number” and adding a condition to the second arrow saying “the number of the verb phrase must be equal to the variable number.”

Subject-predicate agreement is not the only rule in English grammar best expressed as a side effect in a transition network. On the next page is an ATN for noun phrases taken from Language as a Cognitive Process, Volume 1: Syntax by Terry Winograd (page 598). I’m not going to attempt to explain the notation or the detailed rules here, but just to give one example, the condition labeled “h16p” says that the transition for apostrophe-s can be followed if the head of the phrase is an ordinary noun (“the book’s”) but not if it’s a pronoun (“you’s”).

The ATN is equivalent in power to a Turing machine; there is no known mechanism that is more flexible in carrying out algorithms. The flexibility has a cost, though. The time required to parse a string with an ATN is not bounded by a polynomial function. (Remember, the time for an RTN is $O(n^3)$.) It can easily be exponential, $O(2^n)$. One reason is that a context-sensitive procedure can’t be subject to memoization. If two invocations of the same procedure with the same inputs can give different results because of side effects, it does no good to remember what result we got the last time. Turning an ATN into a practical program is often possible, but not a trivial task.

In thinking about ATNs we’ve brought together most of the topics in this book: formal systems, algorithms, language parsing, and artificial intelligence. Perhaps that’s a good place to stop.
The NP network

Roles: Determiner (Det), Head, Describer, Qualifier

Feature Dimensions:
- Number: Sing, Pl; default: empty
- Person (Per): 1, 2, 3; default: 3
- Que: Yes, No; default: No
- Case: Subj, Obj, Poss; default: empty

Initializations, Conditions, and Actions:

;; Sample word problems
make "ann [Mary is twice as old as Ann was when Mary was as old as Ann is now. If Mary is 24 years old, how old is Ann?]
make "guns [The number of soldiers the Russians have is one half of the number of guns they have. They have 7000 guns. How many soldiers do they have?]
make "jet [The distance from New York to Los Angeles is 3000 miles. If the average speed of a jet plane is 600 miles per hour, find the time it takes to travel from New York to Los Angeles by jet.]
make "nums [A number is multiplied by 6. This product is increased by 44. This result is 68. Find the number.]
make "radio [The price of a radio is $69.70. If this price is 15 percent less than the marked price, find the marked price.]
make "sally [The sum of Sally’s share of some money and Frank’s share is $4.50. Sally’s share is twice Frank’s. Find Frank’s and Sally’s share.]
make "ship [The gross weight of a ship is 20000 tons. If its net weight is 15000 tons, what is the weight of the ships cargo?]
make "span [If 1 span is 9 inches, and 1 fathom is 6 feet, how many spans is 1 fathom?]
make "sumtwo [The sum of two numbers is 96, and one number is 16 larger than the other number. Find the two numbers.]
make "tom [If the number of customers Tom gets is twice the square of 20 per cent of the number of advertisements he runs, and the number of advertisements he runs is 45, what is the number of customers Tom gets?]
make "uncle [Bill’s father’s uncle is twice as old as Bill’s father. 2 years from now Bill’s father will be 3 times as old as Bill. The sum of their ages is 92. Find Bill’s age.]
