point of view, the definition of ABST given in the note\(^1\) could be modified to mention matrix D as well, as follows.

Definition 3.1: System \(( N )\) is said to be ABST w.r.t. \( S \) if it possesses a GAS equilibrium point for every function \( g \in S \), every input vector \( I \) and any diagonal matrix \( D > 0 \).

Remark 3.2: From the proof of Theorem 2.1 above, it is clear that the condition \( T \in D_{n} \) ensures that system \(( N )\) is ABST w.r.t. \( S \) in the sense of the definition above. Notice also that absolute stability in the sense of this new definition guarantees stability when the elements of the matrix \( D \) are perturbed as well. In the neural circuit context, the elements of the matrix \( D \) depend on certain resistance and capacitance values which are subject to uncertainties in practical implementations, thus motivating the modification in the definition.

Analyzing the linearized version of system \(( N )\) in the neighborhood of the equilibrium point \( 0 \) we have

\[
\dot{y} = (TG'(y) - D)y \quad (L\hat{N})
\]

where \( G'(y) = (dG_1(y_1)/dy_1, dG_2(y_2)/dy_2, \ldots, dG_n(y_n)/dy_n)^T \) evaluated at the equilibrium \( y = 0 \), and where \( y = x - x_c \). For convenience we rewrite \((L\hat{N})\) in the form below

\[
\dot{y} = (T - D_1)D_2y \quad (L\hat{N}')
\]

where \( D_2 = G'(y) \) is a positive diagonal matrix for all \( y \in \mathbb{R}^n \), and \( D_1 = D(G'(y))^{-1} \) is also a positive diagonal matrix; note that \( G'(y)^{-1} \) is defined (and positive) for all \( y \in \mathbb{R}^n \).

Taking \((L\hat{N}')\) as a reference for our discussion we see that asymptotic stability of \((L\hat{N}')\) provides necessary conditions for ABST of \(( N )\) in the sense of definition 3.1. This is so because local stability is necessary for global stability.

In this context we see that matrix \(( T - D_1)D_2 \) has to have roots with negative real parts for arbitrary diagonal matrices \( D_1 > 0 \) and \( D_2 > 0 \); and this has to do with the classes of matrices defined in the nomenclature. Indeed, the matrix \( T \) has to belong, simultaneously, to class \( A_c \) and \( D_1 \), this is so because: assuming \( D_2 = I \), clearly \( T \) has to belong to \( A_c \); on the other hand, assuming that \( D_1 = \rho I \), with \( \rho > 0 \), we conclude that \( T \) has necessarily to belong to \( D_1 \).

We denote this class by \( T_1 := A_c \cap D_1 \). Note that \( T_1 \subseteq H_0 \) and \( T_1 \subseteq P_\rho \), i.e. \( T_1 \subseteq H_0 \cap P_\rho \).

Defining \( T := A \cap D \), in a similar manner to \( T_1 \), it is known that the inclusion \( D \subseteq T \) holds. It is also worth noting that, within the class \( T \) matrices, we have \( H = D = I = A = T \) and this is not true in general for matrices that are not in \( T \) (see [1] for proofs of these facts).

From the fact that \( T \in T_1 \) is a necessary condition for ABST and, by Theorem 2.1, \( T \in D_1 \) is sufficient, it follows that the inclusion above is also true in the weak case, i.e. \( D \subset T \).

As a result of the discussion above, we make the following conjecture.

Conjecture 3.3: \( T \in T_1 \) is a necessary and sufficient condition for ABST of \(( N )\), where \( T_1 := A_c \cap D_1 \).

However, obtaining a characterization of this class (algorithmic or otherwise), would, in our opinion, be a hard problem since, so far, not even a characterization of class \( D \) is available for the general case. In terms of complexity, the characterization problem may well be NP- or co-NP-complete, since the problem of detecting whether a given matrix is in \( P \) has been shown to be co-NP-complete [7]. On the other hand, testing whether a matrix is in \( D \) or not has polynomial complexity [8].

**Learning a Simple Recurrent Neural State Space Model to Behave Like Chua’s Double Scroll**

Johan A. K. Suykens and Joos Vandewalle

**Abstract**—In this letter, we present a simple discrete time autonomous neural state space model (recurrent network) that behaves like Chua’s double scroll. The model is identified using Narendra’s dynamic back-propagation procedure. Learning is done in “packets” of increasing time horizon.

**I. INTRODUCTION**

The last ten years, Chua’s circuit has become a paradigm for studying chaos [11]. This simple electrical circuit is able to produce complex behavior and to bifurcate from order to chaos [5]. Moreover, Chua’s circuits have been used recently as cells within cellular neural networks instead of classical neurons, leading to phenomena such as, e.g., spiral waves [4], [13], [14]. On the other hand, cellular and generalized cellular neural networks are in itself also able to produce double scroll or n-double scroll-like behavior, respectively, [1], [9], [15], [17]. The latter results were described in continuous time, and design of the networks is based upon mathematical analysis and insight.

In this letter, we propose neural state space models as a general recurrent network architecture, and more specifically, we investigate the problem of learning such a network to behave like a double scroll. The neural state space model can be considered as some general purpose architecture in order to represent or emulate the behavior of some given system and learn its behavior from examples. Like this is done in the CNN universal machine [14], one could also think of arrays of neural state space models but resulting into an overall architecture that is discrete in time as well as in space.

IEEE Log Number 9413219.
This letter is organized as follows: In Section II, we discuss neural state space models, together with dynamic backpropagation. In Section III, a neural state space model is trained to behave as Chua's double scroll.

II. NEURAL STATE SPACE MODELS AND DYNAMIC BACKPROPAGATION

We consider here discrete time autonomous nonlinear systems

$$x_{k+1} = f(x_k)$$

(1)

with state vector $x_k \in \mathbb{R}^n$ and $f(\cdot)$ a continuous nonlinear mapping. Parametrizing $f(\cdot)$ by a multilayer feedforward neural network with
one hidden layer leads to the model

\[ \dot{x}_{k+1} = W \tanh(V \dot{x}_k + \beta), \quad \dot{x}_0 = x_0 \text{ given} \]

(2)

with interconnection matrices \( W \in \mathbb{R}^{n \times n} \), \( V \in \mathbb{R}^{n \times n} \), bias vector \( \beta \in \mathbb{R}^n \), and \( n_\text{h} \) the number of hidden neurons. The hyperbolic tangent function \( \tanh(.) \) is taken elementwise. Such a parametrization makes sense because any continuous nonlinear function can be approximated arbitrarily well on a compact interval by a multilayer perceptron with one or more hidden layers [6, 8, 10].

**Remarks**

- Nonautonomous models in state space form that are parametrized by multilayer perceptrons for doing nonlinear system identification are discussed in [16] and are called "neural state space models." Both process noise and measurement noise can be taken into account. The model (2) corresponds to the deterministic case with zero external input.

- Input/output models parametrized by neural networks such as NARX and NARMAX models are discussed, e.g., in [3]. These models correspond to feedforward networks. The neural state space model (2) on the other hand is recurrent.

- Concerning identifiability, the representation (2) is only unique up to a similarity transformation and sign reversals because the hidden nodes can be permuted and the sign of all the weights associated to a particular hidden node can be changed.

Suppose now \( N \) data \( \{x_k\}_{k=0}^N \) are available and we are interested in minimizing the error between the state \( \hat{x}_k \) of the model (2) and the given \( x_k \). For prediction error algorithms, the aim is then to minimize the following cost function off-line:

\[ \min_{\theta} J(\theta) = \frac{1}{2N} \sum_{k=1}^N [x_k - \hat{x}_k(\theta)]^T [x_k - \hat{x}_k(\theta)]. \]

(3)

Here \( \theta = [W(:,); \, V(\cdot); \, \beta] \) denotes the unknown parameter vector and \( \hat{x}(\cdot) \) is a columnwise scanning of a matrix to a vector. The nonlinear optimization problem (3) has many local optima in general. In case we use a gradient based local optimization method, the gradient of the cost function is given by

\[ \frac{\partial J}{\partial \theta} = \frac{1}{N} \sum_{k=1}^N [x_k - \hat{x}_k(\theta)]^T \frac{\partial \hat{x}_k(\theta)}{\partial \theta}. \]

(4)

where the expression of \( \frac{\partial \hat{x}_k(\theta)}{\partial \theta} \) is generated by a so-called sensitivity model, which is in itself a dynamical system because the network is recurrent (see [12]). Let us denote the model (2) as

\[ \dot{x}_{k+1} = \Phi(\dot{x}_k; \alpha) \]

(5)

with \( \alpha \) an element of the parameter vector \( \theta \). The sensitivity model becomes then

\[ \frac{\partial \dot{x}_{k+1}}{\partial \alpha} = \frac{\partial \Phi}{\partial \dot{x}_k} \frac{\partial \dot{x}_k}{\partial \alpha} + \frac{\partial \Phi}{\partial \alpha} \]

(6)

which is a dynamical system with state vector \( \frac{\partial \dot{x}_k}{\partial \alpha} \in \mathbb{R}^n \) and input vector \( \frac{\partial \Phi}{\partial x} \in \mathbb{R}^n \). The Jacobian \( \frac{\partial \Phi}{\partial x} \in \mathbb{R}^{n \times n} \) is evaluated around the nominal trajectory. In order to write down the derivatives, let us take an elementwise notation for (2)

\[ \dot{x}^i := \sum_j w_{ij}^i \tanh(\sum_r v_{ir}^j x^r + \beta^j) \]

(7)

where \( \{x^i\} \) and \( \{v_{ir}^j\} \) denote, respectively, the \( i \)-th element of a vector and the \( i \)-th entry of a matrix. The time index \( k \) is omitted after introducing the assignment operator "\( \hat{\cdot} \)." Defining \( \rho^j = \sum_r v_{ir}^j x^r + \beta^j \) one obtains

\[ \frac{\partial \Phi}{\partial \dot{x}^i} = \delta^j_i \tanh(\rho^j) \]

\[ \frac{\partial \Phi}{\partial x^i} = v_{ij} \left( 1 - \tanh^2(\rho^j) \right) \delta^j_i \]

\[ \frac{\partial \Phi}{\partial \beta^j} = v_{ij} \left( 1 - \tanh(\rho^j) \right) \]

\[ \frac{\partial \Phi}{\partial \beta^j} = \sum_j v_{ij} \left( 1 - \tanh(\rho^j) \right) \delta^j_i \]

The steepest descent algorithm

\[ \dot{\theta}_{k+1} = \dot{\theta}_k - \eta \frac{\partial J}{\partial \theta} \]

(9)

is called dynamic backpropagation and was introduced by Narendra and Parthasarathy [12]. Here \( \eta \) is the learning rate and \( \dot{\theta}_t \) the \( t \)-th iterate. More advanced local optimization methods are, e.g., quasi-Newton and conjugate gradient algorithms [7].

**III. LEARNING TO BEHAVE AS A DOUBLE SCROLL**

Let us consider now Chua’s circuit

\[ \begin{aligned}
C_1 \frac{dv_{C_1}}{dt} &= G(v_{C_2} - v_{C_1}) - g(v_{C_1}) \\
C_2 \frac{dv_{C_2}}{dt} &= G(v_{C_1} - v_{C_2}) + i_L \\
L \frac{di_L}{dt} &= -v_{C_2}
\end{aligned} \]

where \( v_{C_1}, v_{C_2}, i_L \) denote, respectively, the voltage across \( C_1 \) and \( C_2 \) and the current through \( L \) and \( g(v_{C_1}) \) is a piecewise-linear function consisting of two breakpoints

\[ g(v_{C_1}) = m_0 v_{C_1} + 0.5(m_1 - m_0)|v_{C_1} + B_p| + 0.5(m_0 - m_1) |v_{C_1} - B_p| \]

(11)

By setting the parameters \( 1/C_1 = 9, \, 1/C_2 = 1, \, 1/L = 7, \, G = 0.7, \, m_0 = -0.5, \, m_1 = 0.5, \, B_p = 1 \), the double scroll attractor is obtained [5]. The ODE (10) was simulated by means of a trapezoidal integration rule with constant step length equal to 0.05 for initial state \( x_0 = [0.0365 \, -0.0610 \, -0.1889]^T \). The training set or the orbit to be tracked consists of the first 1000 data points (corresponding to samples in the time interval [0, 50]).

We propose here a simple neural state space model with three hidden neurons and zero bias vector \( \beta \) in (2) for nonlinear system identification. Starting from random initial parameter vectors, it turns out that off-line learning of the complete given orbit of 1000 data points by means of a gradient based optimization method is extremely hard. In fact this does not come as a surprise because it is well-known that learning long-term dependencies with gradient descent is difficult.
In this paper, a discrete time recurrent nonlinear state space model was identified that behaves like Chua’s double scroll. It is well known that learning recurrent networks is more difficult than feedforward networks, especially for systems with complicated dynamics such as chaotic systems. We avoided the use of global optimization methods and proposed a packet method with increasing time horizon (local optimization), which was successful in order to learn the double scroll trajectory, given some initial state. However, more research is needed in general on learning complex behavior by means of recurrent networks.

Experimental Control of Chaotic Behavior of Buck Converter

Gautam Poddar, Krishnendu Chakraborty, and Soumitro Banerjee

Abstract—This letter reports a method for control of chaos in the dc–dc buck converter. The method differs from the existing ones and is particularly useful for piecewise linear systems with switching nonlinearity.

I. INTRODUCTION

Power electronic circuits broadly fall into the category of piecewise linear systems with an overall nonlinear behavior contributed by discrete switching phenomena. It has been shown that such systems can exhibit deterministic chaos [1]–[3], especially in presence of a feedback loop. Since power electronic circuits with current or voltage feedback have wide industrial application, the control of chaos in such systems assumes special importance.

The existing methods for controlling chaos (as surveyed in [4]) generally require complicated computation to be performed on-line or additional periodic reference voltage. The method proposed in this
