**Abstract.** We demonstrate that it is possible to achieve accurate localization and tracking of a target in a randomly placed wireless sensor network composed of inexpensive components of limited accuracy. The crucial enabler for this is a reasonably accurate local coordinate system aligned with the global coordinates. We present an algorithm for creating such a coordinate system without the use of global control, globally accessible beacon signals, or accurate estimates of inter-sensor distances. The coordinate system is robust and automatically adapts to the failure or addition of sensors. Extensive theoretical analysis and simulation results are presented. Two key theoretical results are: there is a critical minimum average neighborhood size of 15 for good accuracy and there is a fundamental limit on the resolution of any coordinate system determined strictly from local communication. Our simulation results show that we can achieve position accuracy to within 20% of the radio range even when there is variation of up to 10% in the signal strength of the radios. The algorithm improves with finer quantizations of inter-sensor distance estimates: with 6 levels of quantization position errors better than 10% are achieved. Finally we show how the algorithm gracefully generalizes to target tracking tasks.

## 1 Introduction

Advances in technology have made it possible to build ad hoc sensor networks using inexpensive nodes consisting of a low power processor, a modest amount of memory, a wireless network transceiver and a sensor board; a typical node is comparable in size to 2 AA batteries [5]. Many novel applications are emerging: habitat monitoring, smart building reporting failures, target tracking, etc. In these applications it is necessary to accurately orient the nodes with respect to the global coordinate system. Ad hoc sensor networks present novel tradeoffs in system design. On the one hand, the low cost of the nodes facilitates massive scale and highly parallel computation. On the other hand, each node is likely to have limited power, limited reliability, and only local communication with a modest number of neighbors. The application context and massive scale make it unrealistic to rely on careful placement or uniform arrangement of sensors.

Rather than use globally accessible beacons or expensive GPS to localize each sensor, we would like the sensors to be able to self-organize a coordinate system.

In this paper, we present an algorithm that exploits the characteristics of ad hoc wireless sensor networks to discover position information even when the elements have literally been sprinkled over the terrain. The algorithm exploits two principles: (1) the communication hops between two sensors can give us an easily obtainable and reasonably accurate distance estimate and (2) by using imperfect distance estimates from many sources we can minimize position error. Both of these steps can easily be computed locally by a sensor, without assuming sophisticated radio capabilities. We can theoretically bound the error in the distance estimates, allowing us to predict the localization accuracy. The resulting coordinate system automatically adapts to failures and the addition of sensors.

There are many different localization systems that depend on having direct distance estimates to globally accessible beacons such as the Global Positioning System [6], indoor localization [1] [14], and cell phone location determination [3]. Recently there has been some research in localization in the context of wireless sensor networks where globally accessible beacons are not available. Doherty et al [4] present a technique based on constraint satisfaction using inter-sensor distance estimates (and a percentage of known sensor positions). This method critically depends on the availability of inter-sensor distance measurements and requires expensive centralized computation. Savvides et al [15] describe a distributed localization algorithm that recursively infers the positions of sensors with unknown position from the current set of sensors with known positions, using inter-sensor distance estimates. However, there is no analysis of how the error accumulates with each inference and what parameters affect the error. By contrast, our algorithm does not rely on inter-sensor distance estimates, is fully distributed, and we can theoretically characterize how the density of the sensors affects the error. Our algorithm is based on a simpler method introduced by one of the authors in [11] but also independently suggested in [9].

Section 2 presents the algorithm for organizing the global coordinate system from local information. We present a theoretical analysis of the accuracy of the coordinate system along with simulation results is presented in section 3. Section 4 reports simulation results that generalize the basic algorithm to include more accurate distance information based on signal strength. Section 5 investigates the robustness of the algorithm to variations in communication radius as well as sensor failures. Section 6 introduces a variation of the coordinate estimation algorithm that tracks moving targets.

## 2 Coordinate System Formation Algorithm

In this section we describe our algorithm for organizing a global coordinate system from local information. Our model of an ad hoc sensor network is randomly distributed sensors on a two dimensional plane. Sensors do not have global knowledge of the topology or their physical location. Each sensor communicates with physically nearby sensors within a fixed distance  $r$ , where  $r$  is much smaller than

the dimensions of the plane. All sensors within the distance  $r$  of a sensor are called its communication neighborhood. In the first pass we assume that all sensors have the same communication radius and that signal strength is not used to determine relative position of neighbors within a neighborhood. Later in sections 4 and 5 we relax both of these constraints. We also assume that some set of sensors are “seed” sensors - they are identical to other sensors in capabilities, except that they are preprogrammed with their global position. This may be either through GPS or manual programming of position. The main point is for the seeds to be similar in cost to the sensors, and for it to be easy to add and discard seeds.

The algorithm is based on the fact that the position of a point on a two dimensional plane can be uniquely described by its distance from at least three non-collinear reference points. The basic algorithm consists of two parts: (1) each seed produces a locally propagating *gradient* that allows other sensors to estimate their distance from the seed and (2) each sensor uses a *multilateration* procedure to combine the distance estimates from all the seeds to produce its own position. The following subsections describe both parts of the algorithm in more detail.

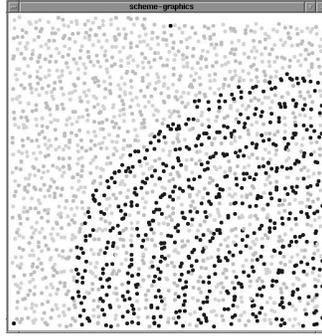

## 2.1 Gradient Algorithm

A seed sensor initiates a gradient by sending its neighbors a message with its location and a count set to one. Each recipient remembers the value of the count and forwards the message to its neighbors with the count incremented by one. Hence a wave of messages propagates outwards from the seed. Each sensor maintains the minimum counter value received and ignores messages containing larger values, which prevents the wave from traveling backwards. If two sensors can communicate with each other directly (i.e. without forwarding the message through other sensors) then they are considered to be within one communication hop of each other. The minimum hop count value,  $h_i$ , that a sensor  $i$  maintains will eventually be the length of the shortest path to the seed in communication hops. Hence a gradient is essentially a breadth-first-search tree [8].

In our ad hoc sensor network, a communication hop has a maximum physical distance of  $r$  associated with it. This implies that a sensor  $i$  is at most distance  $h_i r$  from the seed. However as the average density of sensors increases, sensors with the same hop count tend to form concentric circular rings, of width approximately  $r$ , around the seed sensor. Figure 1 shows a gradient originating from a seed with sensors colored based on their hop count. At these densities the hop count gives an estimate of the straight line distance which is then improved by sensors computing a local average of their neighbors’ hop counts.

## 2.2 Multilateration Algorithm

After receiving at least three gradient values, sensors combine the distances from the seeds to estimate their position relative to the positions of the seed sensors. In particular, each sensor estimates its coordinates by finding coordinates that

**Fig. 1.** Gradients propagating from a seed. Each dot represents a sensor. Sensors are colored based on their gradient value.

minimize the total squared error between calculated distances and estimated distances. Sensor  $j$ 's calculated distance to seed  $i$  is:

$$d_{ji} = \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2} \quad (1)$$

and sensor  $j$ 's total error is:

$$E_j = \sum_{i=1}^n (d_{ji} - \hat{d}_{ji})^2 \quad (2)$$

where  $n$  is the number of seed sensors and  $\hat{d}_{ji}$  is the estimated distance computed through gradient propagation. The coordinates that minimize least squared error can be found iteratively using gradient descent. More precisely, the coordinate estimate starts with the last estimate if it is available and otherwise with the location of the seed with the minimum estimated distance. The coordinates are then incrementally updated in proportion to the gradient of the total error with respect to that coordinate. The partial derivatives are:

$$\frac{\partial E_j}{\partial x_j} = \sum_{i=1}^n (x_j - x_i) \left(1 - \frac{d_{ji}}{\hat{d}_{ji}}\right) \text{ and } \frac{\partial E_j}{\partial y_j} = \sum_{i=1}^n (y_j - y_i) \left(1 - \frac{d_{ji}}{\hat{d}_{ji}}\right) \quad (3)$$

and incremental coordinate updates are:

$$\Delta x_j = -\alpha \frac{\partial E_j}{\partial x_j} \text{ and } \Delta y_j = -\alpha \frac{\partial E_j}{\partial y_j} \quad (4)$$

where  $0 < \alpha \ll 1$ .

### 3 Analysis

In this section we analyze the accuracy of the coordinate system produced by this algorithm. In particular we are interested in the effect of the random distribution of sensors and the average local neighborhood size on the accuracy of

the position estimates. Accuracy is measured by computing the average absolute error (distance) between the actual physical location and the logical position. The error comes from two sources: (1) errors in the distance estimates produced by gradients and (2) errors produced by combining the distance estimates using multilateration.

For the purpose of analysis, the sensors are assumed to be distributed independently and randomly on a unit square plane. This means that for each sensor we choose a random  $x$  coordinate and random  $y$  coordinate on the unit square, independently of all other sensors. The probability that there are  $k$  sensors in a given area  $a$  can be described by a Poisson distribution [10].

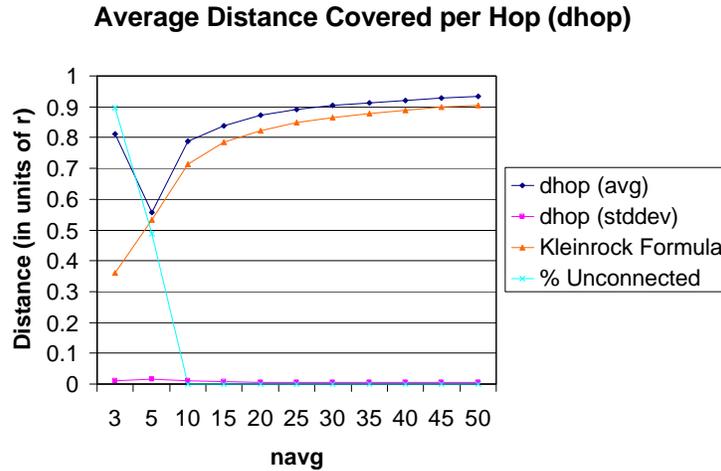

$$Pr(k \text{ sensors in area } a) = \frac{(\rho a)^k}{k!} e^{-\rho a}$$

From this formula, we can derive the expected number of sensors in area  $a$  to be  $\rho a$ .  $\rho$  is equal to  $\frac{N}{S}$  where  $N$  is the total number of sensors and  $S$  is the total surface area. The value that we are interested in is the expected number of sensors in a local neighborhood, which we will call  $n_{local}$ . A sensor communicates with all other sensors within the communication radius  $r$ . Thus the expected local neighborhood  $n_{local}$  is  $\rho \pi r^2$ . In reality the sensors are randomly distributed but would probably not arbitrarily overlap, which reduces the variance in local neighborhood sizes. This random distribution represents a worst case analysis where sensors may overlap arbitrarily.

### 3.1 Error in Distance Estimate

The first source of error in distance estimate arises from the discrete distribution of sensors. A gradient computes the shortest communication path from the source to any sensor. Let the gradient value of sensor  $i$  be  $h_i$ , then the distance between sensor  $i$  and the source is at least  $h_i \times r$ . In the ideal case the gradient value is equal to the straight-line distance, which would imply that with each communication hop one moved a distance  $r$  closer to the source. However given any two sensors, there may not be enough intermediate nodes for the shortest communication path to lie along the straight-line path between the source and destination. In that case, the gradient value overestimates the actual distance between the sensor and the source. Intuitively this is related to the density of sensors within a local neighborhood.

We can characterize the effect of density on the error using results derived in the context of random plane graphs and packet radio networks. In these models, receivers are spatially distributed (usually randomly) and each receiver communicates via broadcast with all neighbors within a fixed radius. The goal is usually to guarantee connectivity and optimize network throughput. Shivendra *et al* showed that the theoretical expected local neighborhood  $n_{local}$  to ensure connectedness is between 2.195 and 10.526 and simulation experiments suggest at least 5 [13]. Silvester and Kleinrock proved that  $n_{local} = 6$  produces optimal network throughput for randomly distributed receivers [7]. In the process they

**Fig. 2.** Theoretical and experimental values for the average distance covered in one communication hop  $d_{hop}$ , for different expected local neighborhoods  $n_{local}$ . There is significant improvement below  $n_{local} = 15$ , after which increasing the neighborhood size has diminishing returns.

derived a formula for how the expected distance covered in one communication hop is affected by the parameters of the random distribution. The expected distance covered per communication hop,  $d_{hop}$ , is the physical distance between a pair of sensors divided by the expected number of hops in the shortest communication path. Kleinrock and Silvester [7] showed that  $d_{hop}$  depends only on the expected local neighborhood  $n_{local}$ , not the total number of sensors.<sup>1</sup>

$$d_{hop} = r(1 + e^{-n_{local}} - \int_{-1}^1 e^{-\frac{n_{local}}{\pi}(\arccos t - t\sqrt{1-t^2})} dt) \quad (5)$$

In Figure 2, we numerically compute and plot  $d_{hop}$  for different  $n_{local}$  using this formula. From this graph we can see that when the expected number of local neighbors is small, the distance covered per communication hop is small and the percentage of disconnected sensors is large. But as the expected local neighborhood increases, the probability of nodes along the straight-line path increases rapidly until  $n_{local} = 15$ , when further increases in local sensor density has diminishing returns. Hence the analysis suggests  $n_{local}$  of 15 to be a critical threshold for achieving low errors in the distance estimates.

<sup>1</sup> Since  $n_{local}$  is proportional to  $N/S$  where  $N$  is the total number of sensors, it would seem odd to say that the formula does not depend on the total number of sensors. However if  $n_{local}$  is kept constant and  $N$  is increased (which implies the total area  $S$  must increase), then  $N$  has no effect. Hence it is appropriate to say that  $d_{hop}$  depends on only  $n_{local}$ .

In Figure 2, we also show the measured value of the average distance covered per hop for different  $n_{local}$ , averaged over several simulations of a gradient from a random source. We also show the percentage of unconnected sensors. The result confirms that the average distance covered per hop does vary as predicted by Kleinrock and Silvester. The formula slightly under-predicts  $d_{hop}$  due to an approximation made in the proof when the source and destination are close. Also, the simulation results suggest  $n_{local}$  of at least 10 is necessary to significantly reduce the probability of isolated sensors.

**Improving the Distance Estimate through Smoothing** Even in the ideal case of infinite density, the distance estimates produced are still integral multiples of the communication radius  $r$ . This low resolution adds an average error of approximately  $0.5 r$  to the distance estimates. Therefore we expect the error to asymptote around  $0.5 r$ .

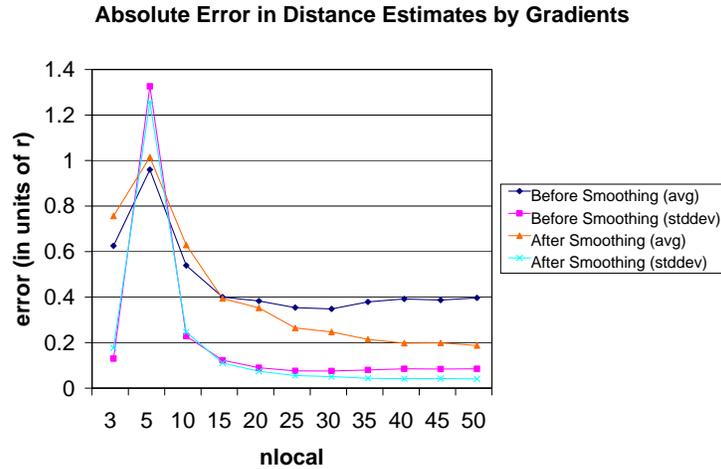

The gradient distance estimate is improved by using local averaging. Each sensor collects its neighboring gradient values and computes an average of itself and neighbor values.

$$s_i = \frac{\sum_{j \in nbrs(i)} h_j + h_i}{|nbrs(i)| + 1} - 0.5 \quad (6)$$

where  $h_i$  is the gradient value at sensor  $i$  (in other words, the integral distance estimate in units of  $r$ ).  $nbrs(i)$  are all the sensors within the communication radius  $r$  of sensor  $i$ .

Intuitively, sensors can determine if they are on the edge of the band by noticing that a large fraction of their neighbors have an integral distance estimate one lower or one higher than their own. The larger the fraction, the closer they are to the edge. The formula is derived from the effect of smoothing a gradient on a linear array of evenly spaced sensors where it produces the perfect distance (formal derivation in [11]). However in our model the sensors are not evenly spaced and there are variations in density even within a neighborhood. The variations in density are the main source of error in the smoothing process.

**Simulation Results on Distance Error** Figure 3 shows results from simulation experiments that calculate the average absolute error in the integral distance estimates for different values of  $n_{local}$ . To vary  $n_{local}$ , the total number of sensors  $N$  is changed while keeping  $S$  and  $r$  constant. This keeps the physical diameter of the network (in units of  $r$ ) constant across all simulations, so that all experiments are equally affected by any errors correlated with distance. In each simulation a gradient is produced by a randomly chosen sensor in the lower left corner. The data point for each value of  $n_{local}$  is averaged over 10 simulations. The absolute error for a sensor  $i$  is computed as  $error_i = h_i d_{hop} - d_i$ , where  $h_i$  is the gradient value,  $d_i$  is the Euclidean distance between sensor  $i$  and the source, and  $d_{hop}$  is the expected distance covered per hop calculated using

**Fig. 3.** Average error in gradient distance estimates for different  $n_{local}$ . Significant improvements are seen in the integral distance estimates for  $n_{local} < 15$ . Beyond 15 there is improvement when the distance estimates are smoothed.

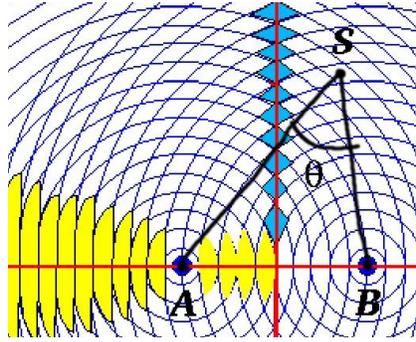

formula 5. This takes into account the fact that  $d_{hop}$  represents the expected distance traveled in one hop for a given sensor density.

The results confirm our earlier analysis. As the value of  $n_{local}$  increases the accuracy of the distance estimate improves, with both the average and standard deviations in error decreasing dramatically. However past  $n_{local} = 15$  the error before smoothing asymptotes at  $0.4r$  due to the limited resolution. Further analysis of these simulations shows that the error does not increase significantly with distance from the source because the majority of the per hop error is removed by using Kleinrock and Silvester’s formula (5). The error is also not correlated with orientation about the source which is an interesting side-effect of choosing a random distribution versus a rectangular or hexagonal grid where there is anisotropy.

For each of the experiments done for integral gradient values, we also calculated the error in the smoothed gradient value for each sensor. The average error results are also plotted in the same figure. The simulation experiments show that for  $n_{local} > 15$  smoothing significantly reduces the average error in the gradient value. Before that the error is dominated by the integral distance error. At  $n_{local} = 40$  the average error is as low as  $0.2 r$ . However the error is never reduced to zero due to the uneven distribution of sensors.

### 3.2 Accuracy of Multilateration

The distance estimates from each of the seeds has a small expected error. We combine these distance estimates by minimizing the squared error from each

**Fig. 4.** Error in position relative to two seeds can be approximated as a parallelogram. The area of this parallelogram depends on the angle  $\theta$ . When  $\theta$  is 90 degrees the error is minimized, however in certain regions  $\theta$  is very small resulting in very large error.

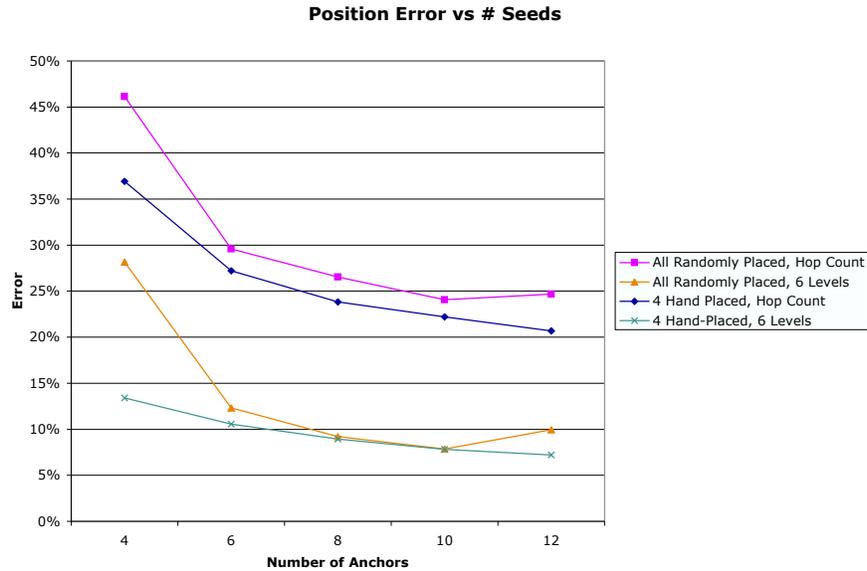

of the seeds using a multilateration formula. Multilateration is a well-studied technique that computes the maximum likelihood position estimation. We use gradient descent to compute the multilateration incrementally.

The seed placement has a significant effect on the amount of error in the position of a sensor. The error in the distance estimate from a single seed is radially symmetric. However, when the distances from multiple seeds are combined, the error varies depending on the position of the sensor relative to the seeds. In Figure 4 the concentric bands around each seed represents the uncertainty of the distance estimate from that seed; the width of the band is the expected error in the distance estimate. The intersection region of the two bands represents the region within which a sensor "may" exist — the larger the region, the larger the uncertainty in the position of the sensor. Hence the error in position of a sensor depends not only on the error in the distance estimates, but also in the position of the sensor relative to the two sources. Let  $\epsilon$  be the expected error in the distance estimates from a seed, and  $\theta$  be the angle  $\angle ASB$ . The overlap region between two bands can be approximated as a parallelogram.

**Theorem 1:** *The expected error in the position of a sensor  $S$  relative to two point sources  $A$  and  $B$  is determined by the area of the parallelogram with perpendiculars of length  $2\epsilon$  and internal angle  $\theta$ . The area is  $\frac{(2\epsilon)^2}{\sin \theta}$ .*

The area of the parallelogram is minimized when  $\theta$  is 90 degrees (square) and when  $\theta$  is very large or very small the bands appear to be parallel to each other resulting in very large overlaps and hence large uncertainty.

As we add more seeds, the areas of uncertainty will decrease because there will be more bands intersecting. If placed correctly the intersecting regions can be kept small in all regions. This analysis suggests first placing seeds along the perimeter to avoid the large overlaps regions behind seeds. However if seeds are inexpensive then another possibility is simply to place them randomly.

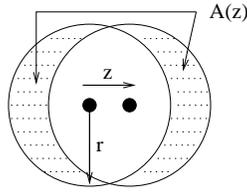

**Fig. 5.** Graph of position error versus number of seeds for two different seed placement strategies. Position error for smoothed hop count and 6 level radio strength distance estimates are shown.

**Simulation results on Position Error** The simulations presented here are motivated by an actual scenario of 200 sensors distributed randomly over a square region  $6r \times 6r$ . This gives a local neighborhood size of roughly 20, which we know from our previous analysis to give good distance estimates. We investigate two seed placement methods: (1) all seeds are randomly placed and (2) four are hand placed at the corners and the rest are randomly placed. Figure 5 shows the location estimation accuracy averaged over 100 runs with increasing numbers of seeds.

We can see that location accuracy is reasonably high even in the worst case scenario with all randomly placed seeds. Accuracy improves with the hand placement of a few. However, the accuracy of both strategies converge as the number of seeds increases and the improvement levels off at about ten seeds. These results suggest that reasonable accuracy can be achieved by carefully placing a small number of seeds when possible or using a large number of seeds when you are unable to control seed placement.

### 3.3 Theoretical Limit on Resolution

There is, in fact, a fundamental limit to the accuracy of any coordinate system developed strictly from the topology of the sensor graph. We can think of each sensor as a node in a graph, such that two nodes are connected by an edge if

**Fig. 6.** A sensor can move a distance  $z$  without changing the connectivity if there are no sensors in the shaded area.

and only if the sensors can communicate in one hop, i.e. they are less than  $r$  distance apart. It is possible to physically move a sensor a non-zero distance without changing the set of sensors it communicates with, and thus without changing any position estimate that is based strictly on communication. The old and new locations of the sensor are indistinguishable from the point of view of the gradient. The average distance a sensor can move without changing the connectivity of the sensor graph gives a lower bound on the expected resolution achievable.

**Theorem 2:** *The expected distance a sensor can move without changing the connectivity of the sensor graph on an amorphous computer is  $(\frac{\pi}{4n_{local}})r$ .*

**Proof:** Let  $Z$  be a continuous random variable representing the maximum distance a sensor  $p$  can be moved without changing the neighborhood. The probability that  $Z$  is less than some real value  $z$  is:

$$F(z) = Pr(Z \leq z) = 1 - e^{-\rho A(z)}$$

which is the probability that there is at least one sensor in the shaded area  $A(z)$  (Figure 6). The area  $A(z)$  can be approximated as  $4rz$  when  $z$  is small compared to  $r$  and we expect  $z$  to be small for reasonable densities of sensors. The expected value of  $Z$  is:

$$E(Z) = \int_0^{\infty} z \dot{F}(z) dz \quad (7)$$

$$= \int_0^{\infty} \rho 4rz e^{-\rho 4rz} dz \quad (8)$$

$$= -ze^{-\rho 4rz} \Big|_0^{\infty} + \left(-\frac{1}{\rho 4r}\right) e^{-\rho 4rz} \Big|_0^{\infty} \quad (9)$$

$$= -\left(z + \frac{1}{\rho 4r}\right) e^{-\rho 4rz} \Big|_0^{\infty} \quad (10)$$

$$= r \left(\frac{\pi}{4n_{local}}\right) \text{ q.e.d} \quad (11)$$

where Equation 9 is by the product rule.

Hence, we do not expect to achieve resolutions smaller than  $\frac{\pi}{4n_{local}}$  of the local communication radius,  $r$ , on an amorphous computer. Whether such a resolution is achievable is a different question. For  $n_{local}=15$ , this implies a resolution limit of  $.05r$ , which is far below that achieved by the gradients.

## 4 Improving Estimates using Inter-sensor Distance Measurements

One virtue of our algorithm is that it can function in the absence of direct distance measurements. At the same time, our algorithm can be easily generalized to incorporate direct distance measurements if available. For example, suppose that sensors are able to estimate the distance of neighboring sensors through radio strength, then these estimates can easily be used in place of  $r$ , or one hop.

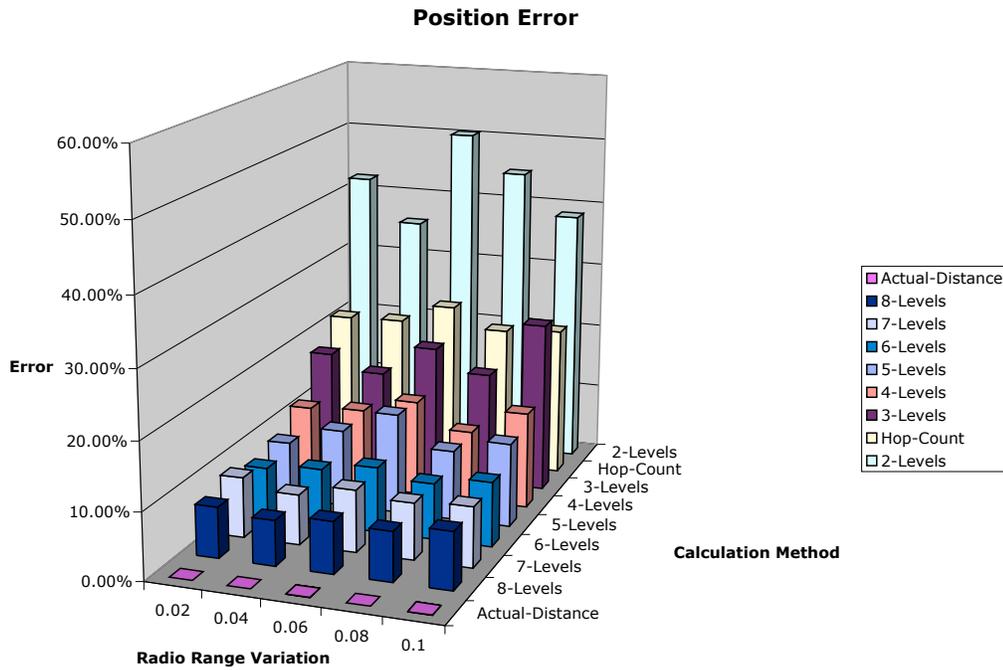

In the signal strength simulation experiments, we show the error in position estimates as we allow multiple levels of quantization. What that means is, for a sensor  $i$  with 2 levels of quantization, it can tell whether its neighbor is within 1 mini hop or two mini hops. Figure 5 shows the position error for the case of six radio levels in the randomly placed and 4 seeds hand placed seed placement regimes for increasing numbers of seeds. First, we can see that six levels of quantization information gives much improved accuracy over smoothed hop count information. Second, like for hop count, the accuracy improves with increased numbers of seeds tapering off at 10 seeds.

Figure 7 shows the effect of different amounts of signal strength information on location estimation accuracy for eight seeds. We see that position accuracy increases with increased levels of quantization. Beyond 7 levels there are diminishing returns. Our original position estimates based on hop count with no quantization yield a position accuracy between 2 and 3 levels of quantizations. This is because we use local averaging to improve the distance estimates. It is unclear how smoothing could be used in conjunction with quantization which we plan to investigate in the future.

We get very high position accuracy with six levels of quantization: error less than 10%. At this level of accuracy with a radius of 20 feet, we could discern locations within 2 feet, which is comparable to commercial GPS. Furthermore, we have found experimentally that this is an achievable level of quantization on the Berkeley mica mote [5] hardware.

## 5 Robustness

Up to this point we have assumed that each of our sensors had the same communication radius  $r$ . In a real-world application we would expect to see variations in radio range from sensor to sensor. Our algorithm can also tolerate variations in communication radius. In Figure 7 we show the error in distance estimate and position estimates when we allow up to 10% random variation in the communication radius. As we can see, the position estimates are reasonably robust

**Fig. 7.** Graph of the effect of 0-10% communication radius variation and different levels of signal strength quantization on location estimation accuracy.

to variation in sensor communication radius, tolerating up to 10% variation in range with little degradation.

The algorithm can also adapt automatically to the death and addition of sensors and seeds. If sensors are added, they can locally query neighbors for gradient values and broadcast their value. If this causes any of their neighbors distances estimates to change then those changes will ripple through the network. As a sensor receives new gradient values it can just factor that into the multilateration process. New seeds simply initiate gradients and any sensor that hears a new seed can then incorporate that seed value into the multilateration process. Prior location estimates will serve as good initial locations for multilateration ensuring fast convergence.

If we assume that sensors randomly fail, then the accuracy is not affected unless the average density falls below 15. If sensors in a region die then this affects the distance estimates because the information will travel around the hole and not represent the true distance. However regional failures can be easily corrected by randomly sprinkling new sensors in that area.

The effect of seed failure depends on their placement strategy. Random placement would be more statistically robust in the face of seed failure. Other place-

ment strategies would be more fragile. In these regimes, sensors have to recognize that seeds have failed to then exclude them from multilateration <sup>2</sup>.

Our algorithm can tolerate a certain amount of random radio failure, because there are multiple redundant paths from seeds to sensors and therefore distance estimates are repeated many times. In general, the error caused by occasional message loss is unlikely to be anywhere close to the error caused by the random distribution of sensors.

## 6 Application to Tracking

Once a coordinate system is established it is then possible to provide a variety of location based services, two of which we briefly describe here. The first is the *position service*, in which a new (and possibly mobile) member of the ensemble is informed of its own location. The second is *tracking* in which the ensemble members collectively track the position of a mobile (and possibly uncooperative) object based on sensor data.

The position service is a simple application of the multilateration framework. When a sensor broadcasts a position service request, every element of the ensemble within the radio range of the sender responds by sending back its own computed location. The requester then captures the location of each replying element and also estimates the distance to that element using radio strength. Since the requester now knows the estimated position and distance to several other elements in the ensemble, it can use multilateration to compute its own position.

The tracking algorithm employs the multilateration framework in conjunction with ad hoc group formation. We describe an algorithm capable of tracking a single target. We assume that each element of the ensemble is equipped with a sensor that can detect and estimate the distance to the target. Each sensor only attends to targets that are no further away than half a radio range; as a result all sensors that sense a target are within one radio range of one another and may therefore communicate with each other using only *local broadcast* which we use to mean that an element transmits a message over its radio, expecting it to be heard by all elements within its radio range and no others.

The elements that can sense the target form an *ad hoc tracking group*; each member of the group sends to the leader its own position and its estimate of the distance between itself and the target. The group leader then employs multilateration to calculate the estimated position of the target. As the target moves, each group member sends updated estimates of distance to the group leader which then re-estimates the position of the target (using the previous estimate as a seed). The target will initially be roughly at the center of the tracking group, surrounded by the group members. Group members drop out of the group when they cease to be able to sense the target.

**Forming the group:** Group formation is based on the leader election algorithm presented in [12]. This is a randomized greedy election algorithm that

<sup>2</sup> perhaps using active monitoring of neighbors' aliveness to produce active gradients.

establishes which sensors are *follower* members of the tracking group and which unique sensor is the group *leader*. Initially, all sensors are neither members nor leaders. When a sensor first senses the target it picks a random number (bounded above by the neighborhood size) and begins counting down to 0. If the sensor counts down to 0 without receiving a *recruit* message from another, it then becomes the group leader and immediately locally broadcasts a recruit message containing its own identity. If, however, a sensor receives a *recruit* message before it has counted down to zero, it becomes a follower group member.

**Estimating Target Position:** When recruited, a follower locally broadcasts a *joining group* message containing its position and its estimate of the distance to the target. Whenever a follower sensor senses a change in the distance to the target it locally broadcasts a *position update* message. The leader captures these distance estimates and periodically uses multilateration to estimate the position of the target.

When a follower sensor notices that it can no longer sense the target it locally broadcasts a *member bailout* message. The group leader then removes this element from the vector of estimated positions and distances. When the group leader notices that it can no longer sense the target, it locally broadcasts a *leader bailout* message. This message contains the identify of that member of the group that the leader estimates is closest to the target. Group members respond to receipt of a leader bailout message in two ways: If the group member is the element named in the bailout message, it immediately becomes the new group leader by locally broadcasts a recruit message. Every other group member, acts as if it had just sensed the target for the first time and begins the countdown of the leader election algorithm. Normally, the follower sensors are recruited by the new leader and the group is reconstituted. However, even if the designated new leader for some reason fails to assume group leadership (for example, the bailout message was garbled in transmission), one of the other sensors will claim leadership and recruit the rest.

We have studied the tracking algorithm by simulating a moving target traversing a path between a series of way points at constant speed. Preliminary results show that the algorithm has positional accuracy comparable to that of the multilateration method used to induce the coordinate system. It also maintains contact with the target quite well, losing the target for about 1% of the cycles.

## 7 Conclusions and Future Work

In this paper, we present an algorithm to self-organize a global coordinate system on an ad hoc wireless sensor network. Our algorithm relies on distributed simple computation and local communication only, features that an ad hoc sensor network can provide in abundance. At the same time it is able to achieve very reasonable accuracy and the error is theoretically analyzable. The algorithm gracefully adapts to take advantage of any improved sensor capabilities or availability of additional seeds. Given that so much can be achieved from so little, an interesting question is whether more complicated computation is worth it. We

are in the process of realizing this algorithm on the Berkeley mote platform [5] towards a implementation of tracking a rover in a field populated by sensors.
