The GJDB Debugger

A debugger is a program that runs other programs, allowing its user to exercise some degree of control over these programs, and to examine them when things go amiss. Sun Microsystems, Inc. distributes a text-based debugger, called JDB, with its Java Developer’s Kit (JDK). I have modified JDB to make its commands look pretty much like GDB, the GNU Debugger\(^1\), which handles C, C++, Pascal, Ada, and a number of other languages. The result is called GJDB (g’jay dee bee)\(^2\). Perhaps the most convenient way to use it is through the interface supplied with Emacs.

GJDB is dauntingly chock-full of useful stuff, but for our purposes, a small set of its features will suffice. This document describes them.

1 Basic functions of a debugger

When you are executing a program containing errors that manifest themselves during execution, there are several things you might want to do or know.

- What statement or expression was the program executing at the time of a fatal error?
- If a fatal error occurs while executing a function, what line of the program contains the call to that function?
- What are the values of program variables (including parameters) at a particular point during execution of the program?
- What is the result of evaluating a particular expression at some point in the program?
- What is the sequence of statements actually executed in a program?
- When does the value of a particular variable change?

---

\(^1\)The recursive acronym GNU means “GNU’s Not Unix” and refers to a larger project to provide free software tools.

\(^2\)This document applies to GJDB version ????.
These functions require that the user of a debugger be able to examine program data, to obtain a traceback (a list of function calls that are currently executing sorted by who called whom), to set breakpoints where execution of the program is suspended to allow its data to be examined, and to step through the statements of a program to see what actually happens. GJDB provides all these functions. It is a symbolic or source-level debugger, creating the fiction that you are executing the Java statements in your source program rather than the machine code they have actually been translated into.

2 Preparation

In this course, we use a system that compiles (translates) Java programs into executable files containing bytecode, a sort of machine language for an idealized virtual machine that is considerably easier to execute than the original source text. This translation process generally loses information about the original Java statements that were translated. A single Java statement usually translates to several machine statements, and most local variable names are simply eliminated. Information about actual variable names and about the original Java statements in your source program is unnecessary for simply executing your program. Therefore, for a source-level debugger to work properly, the compiler must retain some of this superfluous information (superfluous, that is, for execution).

To indicate to our compiler (javac) that you intend to debug your program, and therefore need this extra information, add the -g switch during both compilation. For example, if you are compiling an application whose main class is called Main, you might compile with

```
javac -g Main.java
```

This sample command sequence produces a class file `Main.class` containing the translation of the class `Main`, and possibly some other class files.

3 Starting GJDB

To run this under control of gjdb, you can type

```
gjdb Main
```

in a shell. You will be rewarded with the initial command prompt:

```
[-]
```

This provides an effective, but unfrilly text interface to the debugger. I don’t actually recommend that you do this; it’s much better to use the Emacs facilities described below. However, the text interface will do for describing the commands.

4 Threads and Frames

When GJDB starts, your program has not started; it won’t until you tell GJDB to run it (you tell the program is not started from GJDB’s prompt, which will be [-]). After the
The GJDB Debugger

program has started and before it exits, GJDB will see a set of threads, each one of which is essentially a semi-independent program. If you haven’t encountered Java threads before, the part of your program that you usually think of as “the program” will be the main thread, appropriately named main. However, there will also be a bunch of system threads (running various support activities), that GJDB will tell you about if asked, but which will generally not be of interest. GJDB can examine one thread at a time; which one being indicated by the prompt:

[-] Means there are no threads; the program has not been started.

[?] Means the program is started, but GJDB is not looking at any particular thread. You’ll may see this if you interrupt your program.

name[n] Means that GJDB is looking at thread name, and at frame #n (see below) within that thread.

At any given time, a particular thread is in the process of executing some statement inside a function (method). To arrive inside that method, the program had to execute a method call in a statement of some other method (or possibly the same, in the case of recursion), and so on back to the mysterious system magic that started it all. In other words, in each thread, there is a sequence of currently active method calls, each of which is executing a particular statement, and each of which also has a bunch of other associated information: parameter values, local variable values and so forth. We refer to each of these active calls as frames, or sometimes stack frames, because they come and go in last-in-first-out order, like a stack data structure. Each has a current location, which is a statement or piece of a statement that is currently being executed in that call (sometimes called a program counter or, confusingly, PC). The most recent, or top frame is the one that is executing “the next statement in the program,” while each of the other frames is executing a (so-far incomplete) method call.

For example, consider the simple class Example on page 4. Suppose we start the program with command-line argument 5, and are stopped at statement (E). Then (for the main thread) GJDB sees frames #0–#5, as follows:

<table>
<thead>
<tr>
<th>Frame#</th>
<th>Method</th>
<th>Location</th>
<th>Variables</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>report</td>
<td>(E)</td>
<td>x: 2</td>
</tr>
<tr>
<td>1</td>
<td>ilog</td>
<td>(C)</td>
<td>x: 2, a: 2</td>
</tr>
<tr>
<td>2</td>
<td>ilog</td>
<td>(D)</td>
<td>x: 2, a: 1</td>
</tr>
<tr>
<td>3</td>
<td>ilog</td>
<td>(D)</td>
<td>x: 5, a: 0</td>
</tr>
<tr>
<td>4</td>
<td>process</td>
<td>(B)</td>
<td>x: &quot;5&quot;</td>
</tr>
<tr>
<td>5</td>
<td>main</td>
<td>(A)</td>
<td>args: { &quot;5&quot; }</td>
</tr>
</tbody>
</table>

5 GJDB Commands

This section describes the commands available under GJDB. Except where noted, one uses them when the program being debugged by GJDB is stopped. You can abbreviate most

---

Even when your program is initializing a field in a record, which doesn’t look as if it’s inside a method, it is actually executing a part of either a constructor or a special “static initializer” method (which you’ll see in certain listings under the name <clinit>).
class Example {
    public static void main (String[] args) {
        for (int i = 0; i < args.length; i += 1)
            process (args[i]);          // (A)
    }

    void process (String x) {
        ilog (Integer.parseInt(x), 0); // (B)
    }

    void ilog (int x, int a) {
        if (x <= 1)
            report (a);                  // (C)
        else
            ilog (x/2, a+1);              // (D)
    }

    int report (int x) {
        System.out.println (x);        // (E)
    }
}

Figure 1: A sample program to be debugged. Assume that it is stored in file Example.java.

commands with a sufficiently long prefix. For example, p is short for print, and b is short for break.

5.1 Basic Commands

The following basic commands give you enough to pinpoint where your program blows up, and usually to find the offending bad pointer or array index that is the immediate cause of the problem (of course, the actual error probably occurred much earlier in the program; that's why debugging is not completely automatic.) Personally, I usually don't need more than this; once I know where my program goes wrong, I often have enough clues to narrow down my search for the error. You should at least establish the place of a catastrophic error before seeking someone else's assistance.

help command
    Provide a brief description of a GJDB command or topic. Plain help lists the possible topics.

run command-line-arguments
    Starts your program as if you had typed

    java Main command-line-arguments
to a Unix shell. GJDB remembers the arguments you pass, and plain run thereafter will restart your program from the top with those arguments. By default, the standard input to your program will come from the terminal (which causes some conflict with entering debugging commands: see below). However, you may take the standard input from an arbitrary file by using input redirection: adding < filename to the end of the command-line-arguments uses the contents of the named file as the standard input (as it does for the shell). Likewise, adding > filename causes the standard output from your program to go to the named file rather than to the terminal, and >& filename causes both the standard output and the standard error output to go to the named file.

**where**

Produce a backtrace—the chain of function calls that brought the program to its current place. The commands `bt` and `backtrace` are synonyms.

**up**

Move the current frame that GJDB is examining to the caller of that frame. Very often, your program will blow up in a library function—one for which there is no source code available, such as one of the I/O routines. You will need to do several ups to get to the last point in your program that was actually executing. Emacs (see below) provides the shorthand C-c< (Control-C followed by less-than), or the function key f3.

**up n** Perform n up commands (n a positive number).

**down**

Undoes the effect of one up. Emacs provides the shorthands C-c> and function key f4.

**down n** Perform n down commands (n a positive number).

**frame n** Perform ups or downs as needed to make frame #n the current frame.

**thread T** Make thread T the current thread that GJDB is examining. T may either be the name or the number of a thread (as reported by `info threads`, below).

**print E**

prints the value of E in the current frame in the program, where E is a Java expression (often just a variable). For example

```java
main[0] print A[i]
A[i] = -14
main[0] print A[i]+x
A[i]+Main.x = 17
```

This tells us that the value of `A[i]` in the current frame is -14 and that when this value is added to `Main.x`, it gives 17. Printing a reference value is less informative:

```java
main[0] p args
args = instance of java.lang.String[3] (id=172)
```
This tells you that `args` contains a pointer to a 3-element array of strings, but not what these strings are.

`print/n E` also prints the value of expression `E` in the current frame. If `E` is a reference value, however, it also prints the subcomponents (fields or array elements) of the referenced object to `n` levels. Plain `print` without this specification is equivalent to `print/0`, and does not print subcomponents. Printing subcomponents to one level means printing each subcomponent of `E`'s value as if by `print/0`. Printing to two levels prints means printing each subcomponent as if by `print/1`, and so forth recursively. For example,

```java
main[0] print/1 args
args = instance of java.lang.String[3] (id=172) {
    "A", "B", "C"
}
main[0] p T
T = instance of Tree(id=176)
main[0] p/1 T
T = instance of Tree(id=176) {
    label: "A"
    left: null
    right: instance of Tree(id=178)
}
main[0] p/2 T
T = instance of Tree(id=176) {
    label: "A"
    left: null
    right: instance of Tree(id=178) {
        label: "B"
        left: null
        right: instance of Tree(id=180)
    }
}

dump E
Equivalent to `print/1 E`.

dump/n E
Equivalent to `print/n E`.

info locals Print the values of all parameters and local variables in the current frame.

info threads List all current threads.

quit
Leave GJDB.
5.2 More Advanced Commands

The next bunch of commands allow you to actively stop a program during normal operation.

**suspend and C-f**

When a program is run from a Unix shell, C-c will terminate its execution (usually). At the moment, unfortunately, it will also do this to GJDB itself. When debugging, you usually want instead to simply stop the debugged program temporarily in order to examine it. When the standard input is redirected from a file (using ‘<’; see the run command), you can simply use suspend to stop the program (and then use continue or resume to restart). When the program is running and standard input comes from the terminal, things get complicated: how does GJDB know a command from program input. If you are using GJDB mode (see §7), then C-c C-c will do the trick in this case. Otherwise, if you are running in an ordinary shell, use C-f following by return. And finally, if you are running in a shell under Emacs, use C-qC-f followed by return.

**break place**

Establishes a breakpoint; the program will halt when it gets there. The easiest breakpoints to set are at the beginnings of functions, as in

```
[-] break Example.process
Set breakpoint request Example:8
```

(using the class Example from §4). Use the full method name (complete with class and package qualification), as shown. You will either get a confirming message as above (saying that the system set a breakpoint at line 8 of the file containing class Example), or something like

```
Deferring BP RatioCalc.main [unresolved].
```

when you set a breakpoint before the class in question has been loaded. This means that the breakpoint will be set when (and if) the class in which it occurs is loaded. A place may also indicate a line number in a class, so that you may break on any line of a program. For example, to place a breakpoint at line 13 (point (C)) of the program in Figure 2, type

```
[-] b Example:13
```

(and as you can see, I have abbreviated ‘break’ as ‘b’ just to show it’s legal). Emacs allows you to set breakpoints of this sort with the mouse (see §7). Breakpoints in anonymous classes are a bit tricky; their names generally have the form “C$n” where C is the name of the outermost class enclosing them, and n is some integer. The problem is that you don’t generally know the value of n. GJDB therefore allows “C.0” as a class name, meaning “any anonymous class inside C.”

When you run your program and it hits a breakpoint, you’ll get a message and prompt like this:
Breakpoint hit: thread="main", Example.main(), line=4, bci=22
main[0]

(Here, “bci” indicates a position within the bytecode translation of the method; it is not generally very useful).

**command** \( N \) Add (or delete) commands to breakpoint number \( N \) that will be executed whenever the breakpoint is hit (assuming any conditions on the breakpoint are satisfied). Prompts for commands to be typed in on subsequent lines, ending with a line containing just the word **end**. To delete commands, simply make this trailing **end** be the only line.

**command** As for ‘**command** \( N \)’, above, using the latest breakpoint set as \( N \).

**condition** \( N \) **cond** Make breakpoint number \( N \) conditional, so that the program only stops if \( cond \), which must be a boolean expression, evaluates to true.

**condition** \( N \) Make breakpoint number \( N \) unconditional.

**delete** Removes breakpoints. This form of the command gives you a choice of breakpoints to delete, and is generally most convenient.

**info break** Lists current breakpoints and any conditions or commands on them.

**info watch** Lists current watchpoints (as set by the **watch** command).

**info catch** Lists current exceptions intercepted by GJDB, as set by the **catch** command.

**cont** or **continue** Continues regular execution of the program from a breakpoint or other stop.

**step** Executes the current line of the program and stops on the next statement to be executed.

**next** Like **step**, except that if the current line of the program contains a function call (so that **step** would stop at the beginning of that function), does not stop in that function.

**finish** Does **nexts**, without stopping, until the current method (frame) exits.

**watch** \( P.field \) Stop the program whenever the indicated field is assigned to by the program. \( P \) may either be the name of a class, or an expression in parentheses. If \( P \) is a class name, then all assignments to the given field (of any instance of \( P \)) are caught. If \( P \) has the form (\( E \)), where \( E \) is a non-null reference-valued expression, then \( E \) is evaluated to yield a reference to an object and only assignments to the indicated field of that particular object are watched (however, if the indicated field is static, then all assignments to the field are watched). It is the value of \( E \) at the time the **watch** command is entered that
matters. For example, after ‘watch (L).next,’ changes to the variable L will have no effect on which object is observed.

**watch access** *P.field* Stop the program whenever the indicated field is read by the program (that is, its value is used).

**watch all** *P.field* Stop the program whenever the indicated field is read or assigned to by the program.

**unwatch**... Same arguments as **watch**, but removes the watchpoints set by the corresponding **watch** command.

**unwatch** Remove watchpoints. Provides a choice of which to remove, as for **delete**.

**catch** *class* Stop the program at the point where an exception of type *class* is thrown. GJDB will stop automatically at the throw of any exception that will not be caught. It will not normally stop on exceptions that are caught by the program. The **catch** command directs GJDB to stop on the throw of *class* even if it will be caught. The *class* should be fully qualified, as in *java.io.IOException*.

**ignore** Stop catching exceptions. This form of the command gives you a choice of exceptions to ignore.

### 6 Common Problems

**Name unknown.** When you see responses like this:

```bash
main[0] print x
Name unknown: x
main[0] print f(3)
Name unknown: f
```

check to see if the variable or method in question is static. A current limitation of the debugger is that you must fully qualify such names with the class that defines them, as in

```bash
main[0] print Example.f(3)
```

Beware also that fully qualified names include the package name.

**Ignoring breakpoints.** For a variety of reasons, it is possible for a program to miss a breakpoint that you thought you had set. Unfortunately, GJDB is not terribly good at the moment at catching certain errors. In particular, it will tell you that a breakpoint has been deferred, when in fact it will never be hit due to a class name being misspelled.
7 GJDB use in Emacs

While one can use gjdb from a shell, nobody in his right mind would want to do so. Emacs provides a much better interface that saves an enormous amount of typing, mouse-moving, and general confusion. Executing the Emacs command \texttt{M-x gjdb} starts up a new window running gjdb, and enables a number of Emacs shortcuts, as well as providing a Debug menu for issuing many GJDB commands. This command prompts for a command string (typically \texttt{gjdb classname}) and (for certain historical reasons) creates a buffer named \texttt{*gud-classname*}. Emacs intercepts output from gjdb and interprets it for you. When you stop at a breakpoint, Emacs will take the file and line number reported by gjdb, and display the file contents, with the point of the breakpoint (or error) marked. As you step through a program, likewise, Emacs will follow your progress in the source file. Other commands allow you to set or delete breakpoints at positions indicated by the mouse.

The following table describes the available commands. On the left, you’ll find the text command line, as described in \S 5. Next comes the Debug menu button (if any) that invokes the command. This menu applies both to the GJDB buffer and to buffers containing .java files. Next come the Emacs shortcuts: sequences of keys that run the commands. The shortcuts are slightly different in the GJDB buffer as opposed to buffers containing source (.java) files, so there are two columns of shortcuts. The last column contains further description. Finally, here are a few reminders about Emacs terminology:

1. In shortcuts, \texttt{C-x} means “control-x,” \texttt{S-x} means “shift-x” and \texttt{fn} refers to one of the function keys (typically above the keyboard).

2. The point, in Emacs, refers to the location of the cursor; there is one for each buffer. You can set the point using the usual motion commands when in the buffer, or by simply clicking the mouse at the desired spot.

3. The region in any given buffer is a section of text (usually shadowed or highlighted so that you can tell where it is). One convenient way to set it is by dragging the mouse over the text you want included while holding down the left mouse button.

<table>
<thead>
<tr>
<th>Command</th>
<th>Debug Menu Button</th>
<th>Shortcuts</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>gjdb classname</td>
<td></td>
<td>M-x gjdb</td>
<td>Emacs startup and debugging</td>
</tr>
<tr>
<td>gjdb</td>
<td></td>
<td>M-x gjdb</td>
<td>Debug menu and shortcuts</td>
</tr>
<tr>
<td>gjdb</td>
<td></td>
<td>M-x gjdb</td>
<td>Runtime commands and breakpoints</td>
</tr>
<tr>
<td>gjdb</td>
<td></td>
<td>M-x gjdb</td>
<td>Source file navigation and debugging</td>
</tr>
</tbody>
</table>

---

Finally, here are a few reminders about Emacs terminology:

1. In shortcuts, \texttt{C-x} means “control-x,” \texttt{S-x} means “shift-x” and \texttt{fn} refers to one of the function keys (typically above the keyboard).

2. The point, in Emacs, refers to the location of the cursor; there is one for each buffer. You can set the point using the usual motion commands when in the buffer, or by simply clicking the mouse at the desired spot.

3. The region in any given buffer is a section of text (usually shadowed or highlighted so that you can tell where it is). One convenient way to set it is by dragging the mouse over the text you want included while holding down the left mouse button.
### Table 1: Summary of Commands for Program Control

<table>
<thead>
<tr>
<th>Command Line</th>
<th>Emacs</th>
<th>GJDB buffer</th>
<th>.java buffer</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>next</td>
<td>Step Over</td>
<td>f6 or C-c C-n</td>
<td>f6</td>
<td>Execute to the next statement of the program; if this statement contains function calls, execute them completely before stopping. [See Note 3, below]</td>
</tr>
<tr>
<td>step</td>
<td>Step Into</td>
<td>f5, or C-c C-s</td>
<td>f5</td>
<td>Execute to the next statement of the program; if this statement calls a function, stop at its first line. [See Note 3, below]</td>
</tr>
<tr>
<td>finish</td>
<td>Finish Function</td>
<td>f7 or C-c C-f</td>
<td>f7</td>
<td>Execute until the current function call returns.</td>
</tr>
<tr>
<td>continue</td>
<td>Continue</td>
<td>f8 or C-c C-x</td>
<td>f8</td>
<td>Continue execution of stopped program.</td>
</tr>
<tr>
<td>suspend</td>
<td>Interrupt</td>
<td>C-c C-c</td>
<td></td>
<td>Interrupt execution of program and suspend its threads.</td>
</tr>
<tr>
<td>C-f</td>
<td>Interrupt</td>
<td>C-c C-c</td>
<td></td>
<td>Same as <code>suspend</code>, but works in cases where the debugged program is running and GJDB is passing input to it from the terminal.</td>
</tr>
<tr>
<td>break class:line#</td>
<td>Set Breakpoint</td>
<td></td>
<td>C-x_{ui}</td>
<td>Set a breakpoint at the point (in an Emacs source buffer) or at the indicated class and line number (command line).</td>
</tr>
<tr>
<td>delete class:line#</td>
<td>Clear Breakpoint</td>
<td></td>
<td></td>
<td>Remove a breakpoint at the point (in an Emacs source buffer) or at the indicated class and line number.</td>
</tr>
<tr>
<td>delete</td>
<td></td>
<td></td>
<td></td>
<td>Delete selected breakpoints.</td>
</tr>
<tr>
<td>catch class</td>
<td></td>
<td></td>
<td></td>
<td>Set program to halt whenever exception <code>class</code> is thrown.</td>
</tr>
<tr>
<td>ignore</td>
<td></td>
<td></td>
<td></td>
<td>Stop catching selected exceptions.</td>
</tr>
<tr>
<td>watch C.f</td>
<td></td>
<td></td>
<td></td>
<td>The first three forms set program to halt when (any instance of) field <code>f</code> of class <code>C</code> is accessed. Without a modifier, only assignments to <code>f</code> are tracked. With the modifier <code>access</code>, only uses of <code>f</code>’s value are tracked. The modifier <code>all</code> tracks both types of access. The last three forms are the same, but apply only to the object referenced by <code>E</code> at the time the command is executed. Delete selected watchpoints.</td>
</tr>
<tr>
<td>unwatch</td>
<td></td>
<td></td>
<td></td>
<td>(Re)start the program, using the last set of command-line arguments.</td>
</tr>
<tr>
<td>run</td>
<td>Run</td>
<td></td>
<td></td>
<td>Run <code>gjdb</code> on the class in this buffer.</td>
</tr>
<tr>
<td>quit</td>
<td>Quit</td>
<td></td>
<td></td>
<td>Leave GJDB.</td>
