air, flying micro-robots could fly over terrain which would be impassable for a legged micro-robot. Following the initial vision of Flynn [7], pioneering work in micro-robotic flight was started by Shimoyama (see [20], [12], and [16]) and more recently, milli-robotic flapping flight by Cox *et al.* [2]. Previous work on the MFI has been documented in several areas by Fearing *et al.* [6], Schenato *et al.* [18], Sitti *et al.* [21] and Yan *et al.* [25].

This paper considers the kinematic and power requirements for the MFI and presents the current thorax design for the device. The design, shown in Fig. 1, utilizes planar flexural 4-bar elements to amplify small piezoelectric actuator displacements and a 5-bar spherical differential mechanism to map the motions into flapping and rotational movements.

The design target for the MFI is the blowfly Calliphora, which has a mass of 100 mg, wing length of 11 mm, wing beat frequency of 150 Hz, and actuator power of roughly 8 mW. At this size scale, the current best understanding of non-steady state aerodynamics comes from experimental observations of real insects and kinematically similar mockups, most notably, work by Dickinson *et al.* [3] and Ellington *et al.* [5].

Figure 1a illustrates the proposed components of the MFI. A photo of a mock-up, fabricated to scale (but without actuation), is shown in Fig. 1c. Table 1 summarizes the size and mass specifications of some MFI thorax components.

Thorax components of the MFI. The frames are folded from 12.5 μ m stainless steel shim. Flexures are cut from 6.25 μ m polyester sheets and wings are made from polyimide spincoated down to 7 μ m

2. INSECT UNSTEADY AERODYNAMICS

It has long been known that insect flight cannot be explained by steady state aerodynamics and only in recent years has there been elucidation of the unsteady aerodynamic mechanisms which account for the large lift forces generated. Francis and Cohen appear to have been the first to study impulsive wing translational motions which give rise to the phenomenon known as *delayed stall* [8]; this effect has recently been quantified using a scaled model of a hawkmoth by Ellington *et al.* [5]. Dickinson *et al.* observed that this phenomenon was inadequate in accounting for the total lift and, using Robofly, established two additional important lift mechanisms: *rotational lift* and *wake capture* [4].

RoboFly, shown in Fig. 2, is a dynamically-scaled model of Drosophila (the fruitfly). It consists of two wings, each driven by 3 stepping motors, which can closely mimic the stroke kinematics of Drosophila or follow other arbitrary trajectories. Strain gauges measure instantaneous wing forces and the integral of forces around a closed wing beat cycle can be measured to determine net flight forces. Robofly running with a wing beat frequency of 1/6 Hz in mineral oil has the same Reynold's number as a fruitfly with wing beat frequency 220 Hz in air. By pumping air bubbles into the oil tank, digital particle image velocimetry (DPIV) can be used for flow visualization.

Dickinson *et al.* have found wing trajectories which generate peak lift forces of four times the equivalent insect weight [4]. At the bottom of a stroke, the wing rotates resulting in the *rotational lift* forces. The timing of this rotation can change the net lift from positive to negative, as seen in Fig. 3. The second key finding was the significant force generated by *wake capture* at the top and bottom of the stroke when the wings recover some of the kinetic energy imparted to the air in the previous stroke. These results are directly relevant to the wing kinematics of the MFI, as it appears that a rapid wing rotation of 90° needs to occur before the end of the down stroke to create adequate lift. These three stroke components of force generation can be seen in the flow patterns created by Robofly using DPIV (see Fig. 4). These

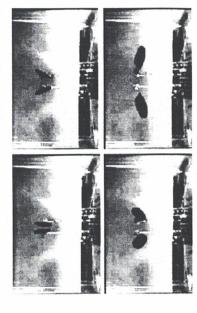

Figure 2. Robofly apparatus in mineral oil tank

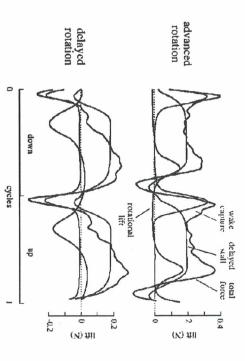

Figure 3. Experimental data from Robofly. The timing of wing rotation has a major effect on net lift. Advanced rotation, before the end of the stroke, significantly increases lift. (Adapted from Dickinson et al. [4].)

force peak is greatest and corresponds to the peak forces seen for advanced rotation (drag) direction. Wake capture is evident at 0.59 of the stroke cycle, where the total (panel 0.46) there is a peak in total force, although mostly directed in the rearward The first panel shows the typical flow and forces during translation. At mid rotation panels begin with the wing moving toward the left, rotating, and reversing direction.

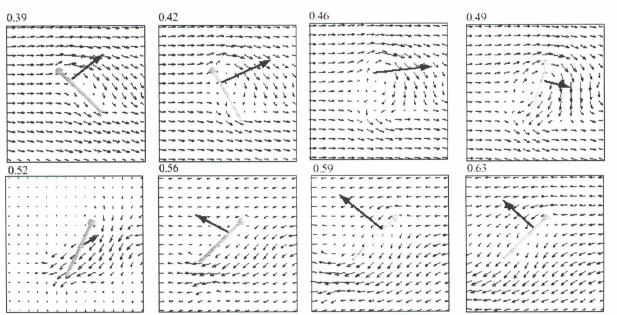

Figure 4. Robofly flow visualization during translation, rotation, and wake capture with images captured at 0.65R (R = wing length). The gray bar shows the wing chord, the circle represents the leading edge and the large arrow indicates the instantaneous force vector. Fluid flow is shown relative to wing motion so that the wing appears to be stationary in the sequence (in the first panel, the wing is actually moving towards the left). The panel numbers indicate the proportion of the complete stroke cycle.

2 degrees of freedom (DOF). frames to control two links of a spherical 5-bar mechanism, permitting the necessary For each wing, the MFI thorax design, illustrated in Fig. 5, uses a pair of 4-bar linkages and cams [17] which is not fully understood and is too difficult to fabricate. of over 90°. The thorax of a biological insect uses a complicated arrangement of rotation [4]. Drosophila uses a wing stroke of 160° combined with wing rotation Insect flight at the centimeter scale requires both large stroke amplitude and wing

3.1. Planar 4-bar kinematic analysis

angle θ_4 is a function of the driven link angle θ_2 : Figure 6a shows a 1 DOF planar 4-bar mechanism with link 1 fixed. The output link

$$\theta_4 = 180^\circ - (\delta_1 + \delta_2),$$
 (1)

$$z = (l_1^2 + l_2^2 - 2l_1 l_2 \cos \theta_2)^{1/2},$$

$$\delta_1 = \cos^{-1} \left(\frac{z^2 + l_1^2 - l_2^2}{2zl_1} \right),$$

$$\delta_2 = \pm \cos^{-1} \left(\frac{z^2 + l_4^2 - l_3^2}{2zl_4} \right).$$
(2)

 $\delta_2 = 0^{\circ}$). The corresponding range for θ_2 can be found by using equation (2). can be found by observing that the minimum angle corresponds to $z = l_3 - l_4$ (easily seen by setting $\delta_2 = 180^\circ$) while the maximum angle corresponds to $z = l_3 + l_4$ (or termined if singularities are avoided. The angular motion range for the driven link tions. and the 4-bar output angles (i.e. $\theta_{AOB} = \theta_{4,lag} + \Delta \theta_{4,lag}$ and $\theta_{EOD} = \theta_{4,lead} + \Delta \theta_{4,lead}$, directly with the wing leading edge and the wing lagging edge, respectively). where the subscripts 'lead' and 'lag' refer to the 4-bar frames associated more plane, as shown. By construction, constant offsets will exist between these angles and are driven about the z-axis by angles θ_{AOB} and θ_{EOD} with respect to the x-zThe planar links AOB and EOD are rigidly attached to the output links of the 4-bars the origin O. The link vertex angles are α , β , γ and δ (such that $\cos \alpha = \mathbf{A} \cdot \mathbf{B}$, etc.). analyzed. Consider the vectors A, B, C, D, E to be on the unit sphere centered about The kinematics of the spherical 5-bar differential shown in Fig. 7a will now be

angles be given by θ : this 4-bar is given by $\zeta = \cos^{-1}(\mathbf{B} \cdot \mathbf{E})$. Let the difference between the driven link mechanisms such as [15] by McCarthy). The vertex angle of the new 'fixed' link of 4-bar (the kinematic analysis for this can be found in a standard text on linkages and Initially, fix θ_{AOB} so that **B** is fixed and the mechanism is reduced to a spherical

$$\theta = \theta_{\text{EOD}} - \theta_{\text{AOB}}.$$

(3)

Next, define new functions $\mu(\theta)$, $\nu(\theta)$, and $\xi(\theta)$:

$$\mu(\theta) = -\sin\beta(\cos\theta\sin\delta\cos\zeta + \cos\delta\sin\zeta),$$

$$\nu(\theta) = \sin \theta \sin \delta \sin \beta,$$

$$\xi(\theta) = \cos \gamma + \cos \beta (\cos \theta \sin \delta \sin \zeta - \cos \delta \cos \zeta). \tag{4}$$

AOB and BOC and can be calculated as: The wing rotation angle ϕ_r is naturally defined as the angle made between planes

$$\phi_r(\theta) = \tan^{-1} \frac{\nu(\theta)}{\mu(\theta)} \pm \cos^{-1} \frac{\xi(\theta)}{\sqrt{\mu^2(\theta) + \nu^2(\theta)}}.$$
 (5)

be uniquely determined if the initial configuration is known and singularities are As with the 4-bar, there are two solutions for this wing rotation but it can also

a simple calculation is to define ϕ_r as the average of the driven link angles (i.e. angle of the physical wing. $\phi_f = (\theta_{AOB} + \theta_{EOD})/2)$; this option suffers from the problem that the calculated flapping values for a specific configuration. One alternative which would allow for flapping angle, in general, may not geometrically correspond well to the flapping between the wing and the stroke plane. Each of these choices provides different the wing leading edge, center of area, wing angular bisector, or the intersection to mind. The flapping angle ϕ_f is not so naturally defined and several candidates come For example, the flapping angle may reasonably be based on motion of

plate is rotated so that it coincides with G, then ϕ_f will be the angle made between center of area G. Consider a flat plate with one edge hinged to the z-axis. If this In this paper, the choice of the flapping angle is based on the motion of the wing

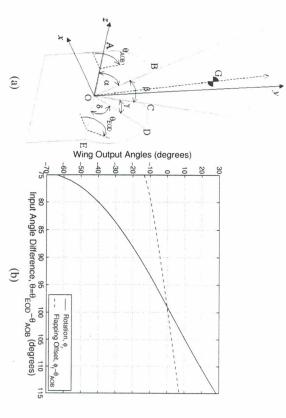

Figure 7. (a) Spherical 5-bar kinematics and (b) Input/Output characteristics with $\alpha = \gamma = \delta = 75^{\circ}$ and $\beta = 30^{\circ}$.

and finding the angle that this projected vector makes with the x-axis. the plate and the +x-axis. This can be found by projecting G onto the x-y plane

built into the structure (e.g. $\Delta\theta_{4,lead} - \Delta\theta_{4,lag} = 98^{\circ}$). It should also be observed that $\phi_r = 0^\circ$ near $\theta = 98^\circ$ and this difference would be the wing differential so a range for ϕ_f of 140° is much more realistic and attainable). optimistically, 153° (this necessitates nearing singularities for both the 4-bars and range is 173° and ϕ_r must have a range of 90°, then the maximum flapping range is, are coupled and one may be increased at the expense of the other. If the input angle that ϕ_f depends on θ but is offset by θ_{AOB} so that only $\phi_f - \theta_{AOB}$ needs to be plotted. For limited input angle ranges for θ_{AOB} and θ_{EOD} , the ranges for ϕ_r and ϕ_f Wing rotation over 90° can be achieved by changing θ over a range of 40°. Notice the output wing rotation and flapping angle characteristics are shown in Fig. 7b. For a wing differential with physical parameters $\alpha = \gamma = \delta = 75^{\circ}$ and $\beta = 30^{\circ}$,

Wing transmission for a micromechanical flying insect

sectional moments of inertia [1]:

$$I_{\text{rect}} = wh^3/12 \text{ and } I_{\text{tri}} = wh^3/36.$$
 (6)

The stiffness of a cantilever beam of length l and modulus E in simple bending due to a concentrated force at the end is given by

$$k = 3EI/l^3. (7)$$

A hollow beam has cross-sectional moment of inertia given by the difference in moments of inertia between a solid beam and a beam smaller by the wall thickness. Hollow beams with an equilateral triangle cross-section, 1 mm on a side, have been constructed by folding a 12.5 μ m stainless steel shim; the beam has an area moment of inertia 1.04 × 10⁻¹⁵ mm⁴ and weighs 0.296 mg/mm. For the same mass, a 37.5 μ m thick, 1 mm wide cantilever beam could be employed but it would only have an area moment of inertia of 4.39 × 10⁻¹⁸ m⁴. Hence, the hollow triangular beam is approximately 240 times stiffer than the solid beam for the same mass (the triangular beam would be marginally stiffer in the orthogonal direction as well). A 5 mm long triangular beam made from 302 stainless steel would have a stiffness of 4500 N/m. A peak load on the structure from the actuators of 100 mN (see Section 4) would deflect the beam only 22 μ m; thus this beam is stiff enough to be employed as links in the 4-bar frames.

Pin joints are difficult to place in a 1 mm structure and they suffer problems with friction, wear, reinforcement, and alignment. Instead, flexures are employed to allow rotational motion between links. Early fatigue testing of steel flexures demonstrated that they would not be suitable (12.5 μ m thick, 125 μ m long flexures last only 10⁴ cycles, 2 orders of magnitude below the desired level). Polyester flexures, 6.25 μ m thick and 125 μ m long, have been tested over 10⁶ cycles without failure and they satisfy the additional need for very low stiffness.

Figure 8a illustrates a sample template for the dual 4-bar mechanism. The stainless steel template can be photo-etched (useful for mass production) or lasercut (useful for rapid prototyping). The template is then folded into the structure shown in Fig. 8b. By keeping the pair of 4-bars on the same template, alignment problems are reduced. Polyester flexures are employed at each of the joints and are glued to the flat template before folding.

Currently, the structures are folded manually using fixtures and bonded using cyanoacrylate adhesive. Automated folding of microstructures is quite feasible, particularly using simple fixtures and a motion planning approach such as that described by Lu and Akella in [13]. Tools for microassembly have been described by Shimada *et al.* [19] and by Thompson and Fearing [24].

Lightweight wings are fabricated with a polyimide spincoating step resulting in a final thickness of 7 μ m. The wings are reinforced with 200 μ m diameter polyimide tubes to provide rigidity. Each wing weighs 0.5 mg and has an inertia moment of 20 mg mm². Figure 9 shows the resulting wing beside the wing of a blowfly

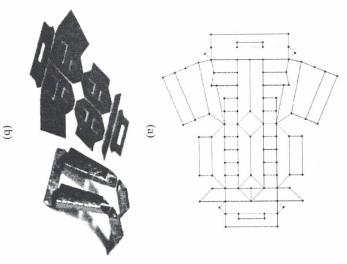

Figure 8. (a) Flat pattern for thorax dual 4-bar flexural frame and (b) photo of laser-cut sheet before and after folding.

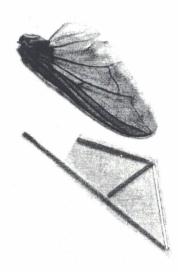

Figure 9. Photo of 0.5 mg polyimide wing, shown with Calliphora wing for comparison.

for comparison. Figure 10 illustrates a sample trajectory for the wing when it is attached to the thorax.

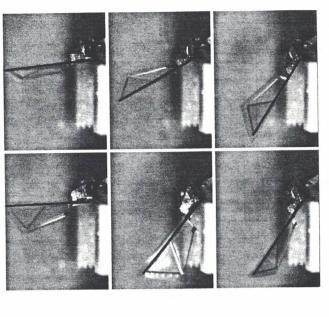

Figure 10. Clockwise sequence of images for a wing prototype driven at 100 Hz with a rotation range of over 90° and flapping range of 80°. The dark line indicates the leading edge of the wing. The first 3 images in the sequence (starting from the top left) illustrate wing rotation at the end of a stroke.

4. ACTUATION

The basic MFI actuator is the piezoelectric unimorph, illustrated in Fig. 11 and described by Sitti *et al.* in [21]. The beam theory for unimorph actuators is well established [22] and they have been used previously by Cox *et al.* for flapping mechanisms [2]. The MFI unimorph consists of a single-crystal PZN-PT piezoelectric layer bonded to a steel elastic layer. Application of an electric field across the piezoelectric layer gives rise to longitudinal and transverse strains which lead to bending.

For a flapping mechanism with a wing load on it, design parameters such as unimorph dimensions, output torque, resonant frequency, transmission ratio, quality factor, weight, *etc.* must be selected for optimal performance.

For simplicity, consider only the flapping degree of freedom for the following analysis. The unimorph actuator motion is amplified through the proposed thorax design described in Section 3. Consider a wing load of inertia J_w and damping B_w , and a 4-bar mechanism with stiffness K_t and stroke amplification (transmission

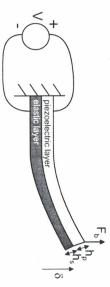

Figure 11. Basic cantilevered rectangular shape unimorph actuator structure.

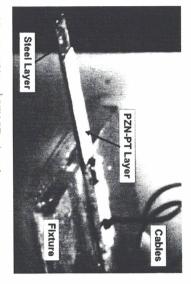

Figure 12. Photo of $5 \times 1 \times 0.22 \text{ mm}^3 \text{ PZN-PT}$ unimorph.

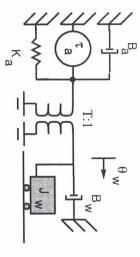

Figure 13. Linear dynamic model of piezo actuator, lossless transmission, and wing.

ratio) T. A linear approximate dynamic model of Fig. 13 gives:

$$J_{\mathbf{w}}\ddot{\phi}_{\mathbf{f}} + B_{\mathbf{w}}\dot{\phi}_{\mathbf{f}} + \left(\frac{K_{a}}{T^{2}} + K_{\mathbf{t}}\right)\phi_{\mathbf{f}} = \frac{\tau_{a}}{T},\tag{8}$$

where ϕ_{Γ} is the flapping stroke angle, K_a is the actuator rotational stiffness and τ_a is the actuator torque input. Here, the actuator damping B_a and inertia J_a are assumed to be negligible with respect to the load damping and inertia.

Wing transmission for a micromechanical flying insect

For a given load power requirement, the actuator dimensions are to be chosen for ease of mechanical drive, fabrication, and drive voltage requirements. Considering the MFI specifications described in Section I, the net wing lift force must match the insect weight of 1 mN. In the quasi-steady state, lift and drag forces are proportional to the square of velocity; however, to simplify the analysis here, a linear damper is chosen with a force at peak wing velocity equal to the MFI mass for an upper bound; this is a conservative estimate because the linear damper overestimates the damping force for all wing velocities less than the peak velocity. Hence the wing damping B_w (at the wing hinge) can be approximated as:

$$B_{\rm w} \approx \frac{mgl_{\rm w}}{\omega\Phi_{\rm f}} = 8.65 \times 10^{-9} \,\mathrm{N} \cdot \mathrm{s} \cdot \mathrm{m},$$
 (9)

where m=100 mg, g=9.81 m/s², $l_{\rm w}=10$ mm (distance to the wing center of pressure), $\omega=2\pi$ (150 Hz), and $\Phi_{\rm f}=70^{\circ}$ is the wing flapping amplitude at resonance.

The quality factor Q of a resonant system is defined as the ratio of stored energy to energy dissipated per radian. With proper actuator and transmission design, energy dissipation for the MFI is work done on moving air, i.e. useful work. A high Q hence implies large internal stored energy, and poor controllability of wing amplitude and phase due to actuator saturation. Sotavalta showed that blowflies have a relatively low Q, estimated on the order of 1-3 [23]. The quality factor for the thorax and wing should be about $Q_w = 2.5$, as a higher Q_w system requires a lower transmission ratio and less actuator motion at DC. A lower Q_w results in a more manoeuverable wing.

The wing inertia is given by:

$$J_{\rm w} = \frac{Q_{\rm w} B_{\rm w}}{\omega} = 2.26 \times 10^{-11} \text{ kg} \cdot \text{m}^2.$$
 (10)

The actuator stiffness, as seen at the wing hinge, must resonate at ω ; hence:

$$K_1 = K_a/T^2 + K_t = J_w \omega^2 = 2.0 \times 10^{-5} \,\text{N} \cdot \text{m}.$$
 (11)

The four-bar transmission converts the small rotation of the actuator θ_a to the wing rotation ϕ_f by a transmission ratio T. At DC, the displacement of the wing is just:

$$\phi_{\rm f,dc} = \frac{T\tau_a}{K_1} = \frac{2\Phi_{\rm f}}{Q_{\rm w}} = T\theta_{\rm a,dc}. \tag{12}$$

Then, for a given T and the desired wing flapping amplitude Φ_f at resonant frequency ω :

$$\tau_{a} = \frac{2K_{1}\Phi_{f}}{TQ_{w}} = \frac{\phi_{f,dc}K_{1}}{T},$$

$$\theta_{a,dc} = \frac{\phi_{f,dc}}{T} = \frac{2\Phi_{f}}{TQ_{w}}.$$
(13)

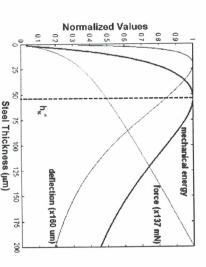

Figure 14. The effect of steel elastic layer thickness h_s on normalized values of the deflection δ_{de} , the blocking force F_b , and the stored energy E_s for a 5 mm \times 1 mm PZN-PT unimorph with $h_p=136~\mu$ m and applied voltage of 200 V.

For a given h_s , h_p and V. I and ω can be computed as

$$I = \frac{h_{\rm p}^2 D}{3d_{31} AB(B+1)V} \theta_{\rm a.d.c.}$$

$$\omega = \frac{4s_p}{3d_{31} h_{\rm p} V} \frac{AB+1}{AB(B+1)} \tau_{a.}$$

(14)

The average power at the wing is also another important parameter for the design which can be computed from

$$P_{w} = \frac{\tau_{a}^{2} B_{w}}{8T^{2} (B_{w} + B_{a}/T^{2})^{2}} = \frac{(mg I_{w})^{2} B_{w}}{2(B_{w} + B_{a}/T^{2})^{2}},$$
(15)

where $B_a = K_a/(Q_a \omega)$, $Q_a = 20$ and $K_a = T^2(K_1 - K_t)$.

In Fig. 14, the PZN-PT layer is fixed at $h_p = 127~\mu m$ while h_s is varied to see how it affects the normalized values of δ_{dc} , F_b and f_r . The energy stored E_s in the unimorph reaches a maximum at $h_s^* = 53.6~\mu m$. Table 3 shows the optimized E_s values for various PZN-PT unimorph thicknesses. E_s increases as h_p decreases but h_p has a minimum practical value based on the ability to polish the PZN-PT (the material is very brittle and current polishing techniques damage slabs thinner than 90 μ m), the applied electric field (data sheets from www.trsceramics.com show crystals tested up to 120 kV/cm so an operating voltage of 200 V implies that 17 μ m is a sufficient thickness to survive), and the ultimate tensile strength of the PZN-PT.

Based on the desired $Q_{\rm w}$, and dissipated power in a cycle, the desired $E_{\rm s}$ can be determined to be 30 μ J. Thus, from Table, the unimorph width can be increased to 4.3 mm for the 90 μ m thick PZN-PT to give the equivalent stored energy (alternatively, the applied voltage might be increased above 400 V). Since this is

Calculated energy storage for 5 mm \times 1 mm PZN-PT unimorph subjected to 200 V for different $h_{\rm p}$ and $h_{\rm s}$ values.

the total unimorph mass and there will be 4 actuators total, each unimorph would have dimensions 5 mm \times 1.1 mm \times (90 μ m PZN-PT + 35.6 μ m steel) and weigh 5 mg, as indicated in Table 1.

5. CONCLUSION

At this stage in the MFI design, a good understanding of the necessary wing kinematics, forces, velocities and power has been developed from measurements on Robofly and real insects. Kinematic structures at the desired size scale have been fabricated using folded stainless steel to give adequate wing motion when driven by piezoelectric unimorph actuators. Polyester flexures employed at the joints between links have been tested over 106 cycles without failure, exceeding the original specifications. Instrumentation of the MFI with strain gauges and other sensors will permit the wing forces to be quantified. Closed-loop wing controllers are being developed to react to wing forces and modify wing stroke patterns as needed to achieve stable flight.
